The first combinatorial antibody libraries were prepared from hyperimmunized mice and were constructed in the lytic bacteriophage lambda. Total RNA taken from mouse spleen was reverse-transcribed, and antibody heavy chains (Fd of IgG1, V_H and C_{H1} domains) and light chains (V_L and C_L domains) were PCR-amplified and independently cloned into modified lambda phage vectors. These heavy and light chain libraries were combined, following restriction digestion and religation, to create a single vector capable of expressing Fab fragments derived from the randomly scrambled antibody light and heavy chain genes. To identify Fab fragments specific for the immunizing antigen, the combinatorial library was screened using a filter lift plaque assay. Here, soluble Fabs, released during plaque

formation, were transferred to nitrocellulose filters. Subsequently, the filters were probed with radiolabeled antigen, and plaques formed by a phage encoding antigen-binding Fab were identified by autoradiography.

The successes of the mouse system were followed up by studies seeking to apply the methodology for cloning human antibodies (Fig. 1). The first human combinatorial Fabs were derived from a library prepared using peripheral blood lymphocytes (PBLs) of an individual recently boosted with tetanus toxoid. No specific Fabs, however, were obtained from a similar but nonboosted tissue donor, despite the high anti-tetanus toxoid serum titer in this individual. This failure underscores an important point in constructing human antibody libraries: in the absence of recent boosting, PBLs are a poor source of RNA from specific antibody-producing

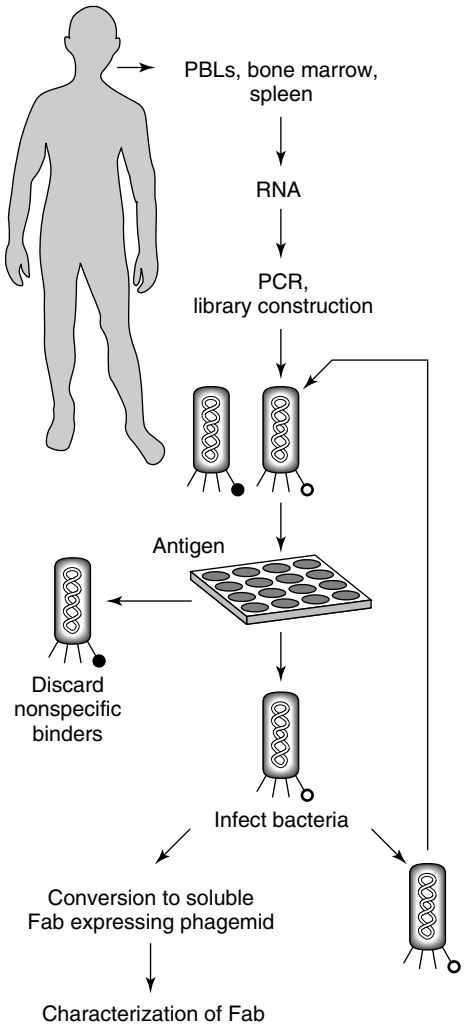

Fig. 1 Strategy for cloning human monoclonal Fab fragments from phage display combinatorial libraries. RNA prepared from antibody-producing tissue sources (e.g. bone marrow and peripheral blood) is reverse-transcribed, and the light chain and Fd portion of the heavy chain are amplified using PCR. The amplified genes are then cloned sequentially into a phagemid vector and ''rescued'' to a phage display library in which each phage expresses Fab on its surface. The library is then ''panned'' over an immobilized antigen, and specific phage Fabs are converted to a soluble Fab-expressing system for further characterization. [Adapted from Burton, D.R. and Barbas, C.F. (1993) *Chem. Immunol.* **56**, 112–126.]

plasma cells. In the resting state, plasma cells will be found in higher numbers in the bone marrow, and this is often a preferable starting point for library construction.

These early experiments illustrated the validity of the combinatorial approach. Despite the disruption of the original *in vivo* heavy–light chain combinations, the frequency of productive Fabs was higher than what may have been envisioned *a priori*. This result can be explained by chain promiscuity – the ability of a particular light or heavy chain to accept a number of different heavy or light chains respectively, while retaining antigen binding.

The lambda phage system, however, was hampered by its inefficient screening procedure. This method is laborious and restrictive of the number of clones that may be examined, which is a limiting factor when working with libraries prepared from sources other than a hyperimmunized one. Furthermore, screening is confined to antigens that are available in large quantities and in a purified form. What was needed was a library system in which positive clones could be affinity-selected by minute quantities of antigen. To address these problems, several groups developed systems to display antibody fragments on the surface of the Ff filamentous phage. We will concentrate here on the pComb3 phagemid vector system. Other systems are described in detail elsewhere.

2.2 Constructing Antibody Libraries on the Surface of a Phage

In vivo, antibody immunity is driven largely by selection. Particular B-cells may be triggered to replicate and differentiate on the basis of recognition of a given antigen by the antibody displayed on their surface. B-cells displaying an antibody that has no specificity for the same antigen will remain passive. In this manner, the immune system is able to home in on an antigenic determinant. Pioneering studies suggested a means by which selection from combinatorial libraries might approximate to native immunity. The work demonstrated ligand-driven selection, or biopanning, from peptide libraries displayed on the surface of a nonlytic filamentous phage. It was reasoned that monoclonal antibodies presented in a similar fashion might also be identified from within a library of many antibody phages by interaction with immobilized antigen. The general scheme for cloning monoclonal antibodies from combinatorial libraries on the surface of a phage is outlined in Fig. 1.

Many different fragments of antibodies have been displayed on phages including Fabs, single-chain Fv (scFv) fragments, and single-domain antibody fragments (including human and camelid antibodies). The absence of antibody constant regions in Fv fragments means that these constructs will not efficiently pair to form an antibody-binding pocket. Therefore, the variable domains must be joined by means of linker sequences using PCR primers. Single-chain antibodies have, however, been shown to reproduce the binding properties of the corresponding whole antibody with varying degrees of efficiency. Note that there are two different types of scFvs: ''light chain first'' and ''heavy chain first,'' and the order can subtly affect the binding properties and stability of the scFv. Another feature of the scFv is that different linker lengths can affect the interaction between the heavy- and light-chain fragments. For example, very short linkers can restrict the heavy-chain fragment such that it will prefer to associate with the light chain of another scFv more readily than with its own light chain, thus producing a

dimer called a *diabody* or a trimer called a *triabody*.

Both Fab and scFv formats are commonly used, and there can be both advantages and disadvantages of an scFv form. The use of splicing overlap extension PCR in scFv library construction reduces the number of restriction enzymes and cloning steps, which may lead to better library diversity. In addition, scFvs are typically produced in much higher yields in *Escherichia coli* than their Fab counterparts. ScFvs may be advantageous when a smaller molecule is desirable, such as for probing narrow cavities. Finally, scFvs, with their tendency to oligomerize, may be exploited for multivalent interactions, although this feature is often a disadvantage when oligomerization is unwanted. Hence, Fabs may be preferable to scFvs if stability is an issue, or if the intention is eventually to generate a whole antibody molecule.

Structurally, the Ff (includes f1, fd, and M13) filamentous phage particle is composed of a closed circular single-stranded DNA genome encapsulated by a long thin protein coat. The majority of the phage particle is composed of approximately 2700 copies of major coat protein 8 (g8p or pVIII), which are distributed along the length of the virion. About five copies of a minor coat protein 3 (g3p or pIII) are arranged at the tail of the phage. The pIII has two ''N-terminal domains'' (N1 and N2) and one C-terminal domain (CT) that are separated by glycine-rich linkers. The N2 domain binds to F′ pili, facilitating infection of male *E. coli*, and N1N2 additionally serves to confer immunity from superinfection by other Ff phages. The membrane-bound CT domain serves to cap the protein to the trailing end of the phage filament. Of the other minor coat proteins, pVI is also present in about five copies with pIII at the tail of the phage, with about five copies each of pVII and pIX deployed at the head.

All the coat proteins on the filamentous phage have been used as fusions for displaying polypeptides on the phage coat, and, to date, all but pVI have been used to display antibody fragments (pVI displays polypeptides via its C-terminus and has been used primarily for cDNA libraries). Although antibody display by pVIII is possible, it has not gained widespread use (see below). An Fab library has been described in which the heavy and light chains are fused to pVII and pIX respectively, and an scFv library based on pIX has been successfully screened to yield novel antibodies. Display by pIX may have the advantage that because the antibody is displayed at the opposite end of the phage from pIII, infectivity is less likely to be affected. Nevertheless, the most common choice by far for antibody display is pIII, and pIII display has proven to be extremely robust.

Filamentous phage are nonlytic and, unlike their lytic counterparts, new virus particles are not formed in the cytoplasm of the host cell for release by lysis. Instead, virions are extruded through the outer membrane, leaving the bacterial cell intact. The extrusion process begins as the filamentous phage particle assembles on the inner bacterial membrane. Then, a pool of pIII molecules is secreted into the inner membrane for incorporation into an emerging phage particle. These pIII molecules are anchored in the membrane via their CT domains, with the remainder of the sequence extending into the periplasmic space. Of the coat proteins, only pIII and pVIII have leader sequences at their N-termini, which are cleaved off in the periplasm during phage assembly.

Drawing from the studies of antibody expression in bacteria described earlier, it seemed reasonable that an antibody fused to the N-terminus of pIII should be able to fold correctly in the environment of the periplasm. The tethered antibody would then be assimilated into the extruding virion and displayed on the surface.

In the earliest phage display experiments, peptides and proteins were fused to pIII by cloning directly the corresponding genes into the phage genome. Consequently, every copy of pIII on the phage surface carried the fusion. In the context of antibody display, the result is multivalent binding and a significant avidity effect, which dramatically hampers the efficiency of selection between antibody clones of different affinities. Thus, monovalent display is preferable for selecting clones with the highest affinity. However, multivalent display of antibody has proved useful in selecting antibodies against a number of targets including those on the cell surface wherein the phage becomes internalized much more efficiently.

To regulate the number of fusion molecules displayed per phage particle, phagemid systems have been developed. Phagemids are simply plasmids containing filamentous phage regulatory elements (typically f1 is used). This sequence contains a filamentous phage DNA origin of replication and a DNA packaging signal. Upon coinfection of a cell with an M13 helper phage, the regulatory element of the phagemid sequesters the replicative machinery provided by the helper phage to package single-stranded phagemid DNA into an infectious phage particle. By introducing into the phagemid a segment of DNA encoding the pIII fusion, subsequent superinfection with the helper phage results in the production of native pIII encoded by the helper phage and the pIII fusion encoded by the phagemid. Tagging a bacterial leader sequence to the front of the pIII fusion serves to direct the translated protein to the bacterial inner membrane. A competition is therefore established between these two forms of the coat protein for incorporation into newly formed phage particles. The resultant phages generally carry one copy of the fusion.

Phagemid vectors have also been constructed to generate antibody fusions with pVIII. This coat protein is present in greater abundance than pIII and covers the entire length of the phage particle; display of up to 24 copies of Fab fused to pVIII has been described. However, there are significant limitations in the size of the protein that can be displayed by pVIII, which are presumably imposed by steric constraints during the phage assembly process. Thus, certain antibodies may not get displayed by pVIII, or the number of copies of antibody per phage may vary considerably leading to poor discrimination of antibodies of high and low affinity. The limits of pVIII display and the associated lack of control over antibody valence during selection have made pVIII display a less favored choice for antibody library construction.

The first vector system developed to display Fab fragments on the surface of filamentous phages via pIII fusion was pComb3. Similar but improved versions of this vector, pComb3H and pComb3X, have since been described, and their use in constructing combinatorial antibody libraries will be examined here by way of example. During the construction of an antibody library, the light and heavy (Fd) chains are cloned sequentially into the vector, effectively randomizing the light and Fd pairings of the recombinant Fabs. In pComb3H, both antibody chains are under the polycistronic control of a single

*lac*Z promoter. The heavy chain possesses a *pel*B leader sequence, whereas the light chain has an *omp*A leader sequence to direct secretion into the periplasmic space in *E. coli*. The Fd chain is fused with a sequence encoding the CT domain of pIII. A five–amino acid tether (GGGGS) is positioned between the Fd and the pIII to minimize interaction. The Fd fragment is thus cotranslated with the pIII CT domain and, following translocation to the periplasm, the fusion protein is anchored to the inner membrane via the pIII domain, with the antibody projecting into the periplasm (Fig. 2). The light chain is then able, given the redox potential of the periplasmic environment, to assemble on the heavy chain to yield a functional Fab fragment. The inclusion of an f1 intergenic region in the vector permits superinfection with an M13 helper phage to be followed by the packaging of single-stranded, phagemid-carrying genes encoding heavy- and light-chain sequences (Fig. 3). Competition between native pIII, comprising the N-terminal domain essential for virion infectivity, and the Fab–pIII fusion yields a phage particle carrying native pIII and monomerically displaying Fab at the head of the filamentous virion. The pComb3X vector is nearly identical to pComb3H except that a hexahistidine and a hemagglutinin (HA) tag are fused to the heavy chain, followed by an amber stop codon and the *gene3* sequence, such that soluble Fab or scFv can be produced readily in nonsuppressor strains of *E. coli* without the need for excising

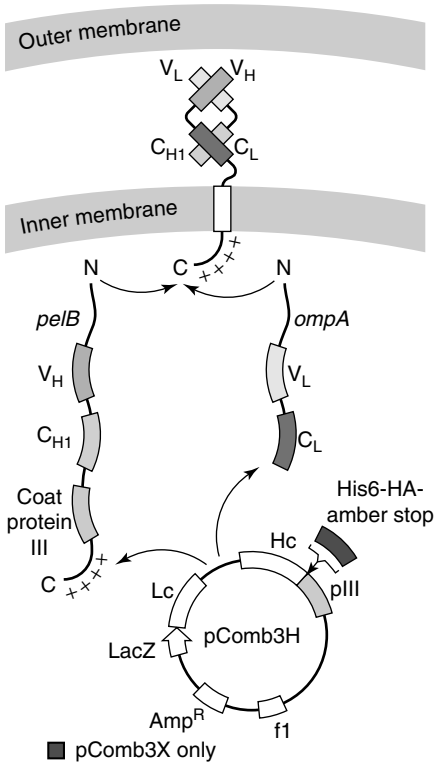

Fig. 2 The proposed pathway of Fab assembly in the bacterial periplasm. Polycistronic expression of cloned light chain (Lc) and Fd (Hc, heavy chain)/pIII fusion is controlled by a single *lac* promoter/operator sequence in pComb3H and pComb3X. Both vectors are improved versions of the original pComb3 vector and have enhanced stability. The pComb3X vector is nearly identical to pComb3H except that a hexahistidine and HA tag followed by an amber stop codon have been inserted in-frame between Fd and *gene3*, allowing for facile detection of the cloned single chain Fvs. The translated antibody is directed to the periplasmic space by *omp*A (Lc) and *pel*B (Hc) leader sequences. Here, the light chain assembles onto the heavy-chain template, which is anchored to the inner membrane by the pIII fusion. (From Barbas et al. (1991) *Methods: A Companion to Methods in Enzymology*, Vol. 2, Academic Press, Orlando, FL, pp. 119–124.)

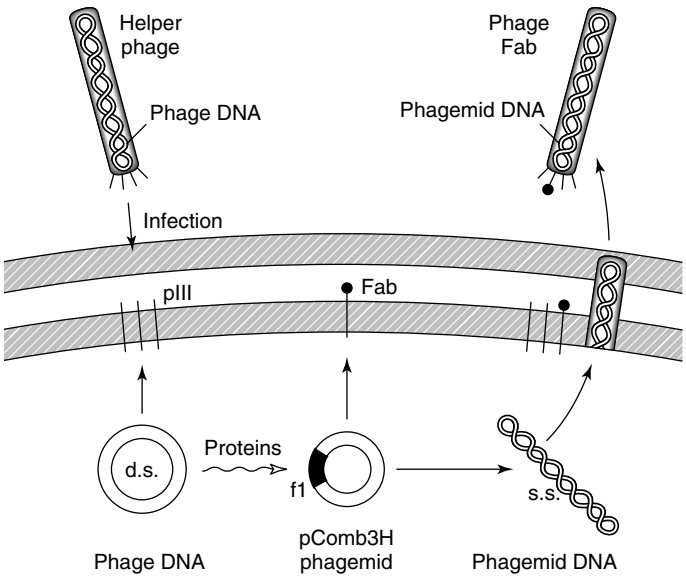

Fig. 3 Helper phage rescue of pComb3H phagemid yielding a phage display library. Incorporation of the f1 origin of replication into the pComb3H phagemid means that upon coinfection with an M13 helper phage, single-stranded pComb3H DNA will be packaged and extruded from the bacterial cell as an assembled phage. As the assembling phage is extruded from the cell, it is ''capped'' by both the native pIII (provided by the helper phage) and the pIII–Fab complex (derived from pComb3H). The resulting phage has Fab displayed primarily monovalently on its surface and contains the corresponding antibody genes inside. [Adapted from Burton, D.R. and Barbas, C.F. (1993) *Immunomethods*, **3**, 155–163.]

gene3. We note that in some phage display systems, the entire *gene3* sequence is incorporated rather than just the CT domain, in the phagemid fusion. Since one function of the amino-terminal half of pIII is to prevent superinfection of *E. coli* by other filamentous phages, in this approach the expression of the phagemid must be halted for helper phage infection and induced for phage display, thus complicating the selection procedure.

Some antibody fragments are poorly displayed on phages. To increase the display of such antibodies on the surface of the phage, some creative strategies have been devised. For example, overexpressing certain chaperones has facilitated increased display and stability of poorly folding antibody fragments. In another example, a random-mutagenesis-selection approach resulted in increased display of antibodies and other polypeptides, the success of which could either be traced to beneficial mutations in the antibody itself or to the leader peptide sequence. Finally, a general strategy for increasing antibody display on pIII has been simply to use a specially designed helper phage that has a defective *gene3*, such that oligovalent display of phagemid-encoded antibody is enforced.

Some alternatives to phage display have been developed in recent years, and two of them deserve particular mention. Yeast

has been used successfully to display scFvs on their surface. Potential advantages of yeast display are that flow cytometry can be used to sort the positive and negative binding clones, and equilibrium binding experiments have shown a good correlation between binding affinity and selection allowing fine discrimination between clones of similar affinity. Ribosome display has also been used to select antibodies in a totally cell-free system. The potential advantages of ribosome display are the large and diverse repertoires that can be achieved (up to $\sim 10^{14}$) and flexibility in selection conditions. The principles of selection for virtually all combinatorial antibody libraries are similar, so because phage display is the most common mode of display, we will next consider the selection from antibody phage libraries.

3 Selection from Antibody Phage Libraries

The strength of phage display lies in the ability to select positive clones occurring in a library at frequencies of one in a million or less. This selection takes place over consecutive rounds of panning in which positive phages are progressively enriched against a background of unwanted clones. In effect, panning is performed by affinity purification of an antibody phage against an antigen immobilized on a solid surface such as a column matrix or a well in an enzyme-linked immunosorbent assay (ELISA) setup. Proteins on the surface of whole cells may also be panned in this manner in tissue-culture plates or using flow cytometry. Phages may also be bound to biotinylated antigen in solution and then captured on streptavidin-coated magnetic beads. In each case, nonantigen-bound phages are removed by thorough washing and bound phages are recovered by elution from the antigen, generally with acid. Eluted phages are infected into *E. coli*, amplified, and reselected in further rounds of panning (see Fig. 4). When monovalent antibody display is used, typically three to five rounds of panning will select a population of clones with the highest affinity for antigen.

The panning process is unlike the antibody response to antigen *in vivo* in which mutation and recombination occur simultaneously with selection. Thus, an antibody library can be screened by alternating antigens in successive rounds to select for cross-reactive antibodies without worrying about "eliciting" *de novo* antibodies to each new antigen. Moreover, it is possible to pan with mutant proteins, unfolded proteins and peptide fragments that are either unsuitable for immunization or are simply not immunogenic. Since panning is not limited by a requirement for purified antigen, phage libraries may be selected against an enormous range of molecules. Panning experiments performed using lysates of virus-infected cells and intact cells indicate that the technique is sensitive to antigen present in small amounts. Different panning strategies are detailed in Section 4.

Antibody clones isolated at the phage level from the final round of panning need to be examined as soluble Fab to further investigate their binding properties. In the pComb3H vector, the transition from phage display to soluble expression is made after removal of the g3 sequence by restriction digestion and religation of the vector. Soluble Fab, which accumulates in the periplasmic space, is released following lysis of the bacteria. If necessary, recombinant Fab may be purified to

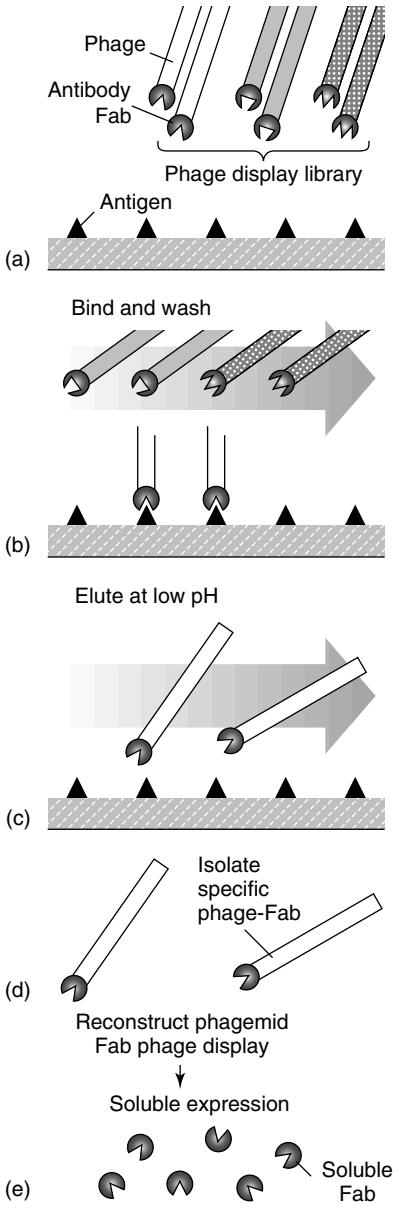

Fig. 4 Panning of the combinatorial phage display library. Phages are incubated with immobilized antigen (a), and unbound phages are removed by washing (b). The remaining phages are eluted in a low pH solution or in the presence of excess soluble antigen (c, d). Eluted phages are then reinfected into bacteria, reamplified, and reapplied to the antigen. Three or four repetitions of steps (a) to (d) result in a progressive enrichment for antigen-specific phage-Fab. Phages from (d) are converted to the phagemid form of the vector, the DNA prepared, and the *gene3* sequence excised. Religation then yields a reconstructed phagemid, which may be used to transform bacteria for the production of soluble Fab (e). [Adapted from Burton, D.R. (1992) *Hosp. Prac.* **27**, 67–74.]

homogeneity from bacterial supernatants in a single step by passage over an anti-Fab affinity column.

For many applications of antibodies, whole immunoglobin molecules are preferred. To this end, a number of vector systems have been assembled, which facilitate rapid subcloning from phage display vectors to eukaryotic expression systems. This presents the opportunity for the investigator to create whole antibodies of any isotype from a phage-selected Fab by joining variable region sequences to the appropriate constant regions contained within the eukaryotic vector.

4
Applications of Combinatorial Antibody Libraries

4.1
Antibodies from Immune Donors

Recombinant antibodies isolated from pComb3-based combinatorial libraries were first prepared from antigenically boosted mice and humans. Specific Fabs have also been generated from humans who have not been actively boosted but who have at some time had contact with

the antigen (e.g. an infectious agent). Preparing combinatorial antibody libraries from immune individuals is advantageous in that the antibody gene repertoires of these donors have been biased in favor of antibodies binding to particular antigens in the course of a natural immune response. In addition, if the subject has been challenged with the antigen on multiple occasions, the available antibodies will probably be of high affinity following rounds of affinity maturation. Combinatorial antibody libraries prepared from a single immune donor can provide a glimpse or a rough ''snapshot'' of an individual's antibody repertoire. This allows a unique opportunity to examine the human humoral immune response to any number of pathogens at the monoclonal level. However, one large caveat should be borne in mind. Library construction shuffles heavy and light chains so that in theory no knowledge of heavy–light chain pairing *in vivo* is available. In practice, many heavy chains may be combined with light chains related to those to which it was paired *in vivo*, but this is extremely difficult to prove for any given case.

One application has been to obtain monoclonal antibodies with antiviral activity, in particular, those antibodies that are best able to neutralize viruses by binding to their surface and diminishing or eliminating their ability to infect host cells. (There are additional and very important effector functions of antibodies, such as their ability to recruit complement and effector cells, but this topic is outside the scope of this review.) In the next section, we will focus on antibody-mediated neutralization, with the acknowledgement that effector functions of antibodies have been found to play a critical role in fighting infectious diseases. Indeed, all neutralizing antibodies (of the appropriate isotype) have effector function capability.

Another potential application of antibody immune libraries is to attempt to understand what deficiencies might exist in the antibody response against certain pathogens, or the nature of immune pathologies in certain tissues. For example, if mostly nonneutralizing antibodies are elicited against a virus, to which epitopes do they bind? What isotypes of antibodies are elicited, how long are the third complementarity-determining regions in the heavy chains (CDR H3s), and what is the degree of somatic mutation? In another example, an antibody library may be constructed from peripheral blood in a tumor or at a site of autoimmune inflammation, so that antibodies selected against these tissues might identify potentially therapeutic or pathologic specificities.

There is no doubt that there are many human antibody specificities of great diagnostic and therapeutic potential that may be cloned from immune donors. When making antibody libraries from immune sources, however, the donor and tissue source should be carefully chosen. The primary prognostic indicator is demonstrable serum antibody reactivity with the antigen to be studied. Serum antibody levels are thought to be predictive of antibody secretion, which in turn reflects the level of specific RNA in plasma cells, and it is this factor that will largely dictate the composition of the library. Although specific antibodies have been isolated from libraries constructed from donors with comparatively low serum titers, libraries prepared from donors with higher titers tend in general to yield a more diverse panel of Fabs. To clone human antibody genes from reverse-transcribed cDNA, human primer sets have been described, which allow the creation of very

diverse libraries covering all functional germ line V genes.

Also critical to library preparation is the choice of tissue source from which specific mRNA can be accessed. In principle, peripheral blood, bone marrow, spleen, tonsil, or lymph node can be used as a starting point for library construction. In humans, bone marrow is known to be a major reservoir of plasma cells that serve to maintain circulating antibody titers and has proven to be an excellent starting point for library construction. In contrast to bone marrow, the number of antibody-producing cells in the peripheral circulation is normally very low. However, if a potential donor is exposed to secondary contact with the antigen, the level of specific plasma cells increases dramatically within around three days postexposure, returning to a resting level a few days later. It has been demonstrated that libraries constructed from peripheral blood lymphocytes obtained during this time frame can yield specific antibodies. Recombinant Fabs have also been isolated from libraries prepared from spleen and tonsil, although these and lymph tissues are not so readily obtained.

To date, the major application of combinatorial libraries derived from immune donors has been in the area of infectious diseases, particularly viruses, although human antibodies have also been selected against bacteria, protozoans, and self and tumor antigens. With respect to viruses, current clinical management of viral infections continues to be inadequate, and at present there are only a handful of antiviral drugs in clinical use in a restricted number of disease states. A significant number of studies, however, suggest that human monoclonal antibodies may prove to be a viable alternative. First, it is well known that specific antibodies are capable of extremely efficient neutralization of a broad spectrum of viruses *in vitro* through a variety of mechanisms. In addition, numerous studies with human serum antibody preparations or rodent monoclonal antibodies have clearly shown the utility of antibodies in preventing an array of viral diseases, if these agents are administered before or shortly after exposure to the pathogen. In a smaller number of cases, neutralizing antibodies have been found to resolve established viral infections, an activity once considered to be mediated exclusively by cytotoxic T-lymphocytes. In humans, the lives of patients suffering from Argentine hemorrhagic fever, induced by Junin virus, can be saved by administration of pooled human sera containing a high titer of Junin virus neutralizing antibodies within eight days of the onset of symptoms. In an animal model of RSV, infection-neutralizing antibodies, administered intravenously or via aerosol at the height of infection, efficiently cleared the virus from the lungs of cotton rats. Antibodies have also been shown to clear viral infections from immunocompromised mice, including persistent virus infections of neurons, which are not recognized by CD8+ cytotoxic T-lymphocytes because the cells are deficient in molecules of the class I major histocompatibility complex. The potential of antibodies has also been demonstrated in passive transfer studies in animal models in which sterilizing immunity against viral challenge has been achieved.

Nevertheless, most commonly, an antibody does not provide sterilizing immunity against natural viral infection. Rather, the prevailing view has been that an antibody acts by reducing the viral load to allow the innate and the adaptive cellular arm of immunity to clear the remaining infection. Indeed, neutralizing antibodies are essential to the success of the vaccines against

major viral infections. In summary, there is a significant body of evidence underlining the proven and potential role of antibodies in prevention and therapy of viral infection. Sections 4.1.1 and 4.1.2 describe the application of phage antibody libraries in the generation of recombinant Fabs against clinically important pathogens and tumor-associated antigens.

4.1.1 Antibodies against Viruses and Prions

We have extensive experience in recovering and characterizing antibodies against viruses (particularly HIV-1) and prion proteins and will therefore present some of these antibodies as examples in this section. One of the first human phage display antibody libraries taken from an immune source was prepared using bone marrow from an individual who had been infected for several years with HIV-1 but was asymptomatic. As would be expected, the patient showed strong serological reactivity against the HIV-1 surface glycoprotein gp120. By panning the library phage against recombinant gp120 immobilized on ELISA wells, it was possible to isolate a large number of recombinant Fabs reacting with the panning antigen, but not with wells coated with bovine serum albumin.

DNA sequences from the variable domains of these 33 positive clones revealed that 10 clones possessed unique heavy chains and 20 clones possessed unique light chains. The sequencing data revealed a phenomenon termed *chain promiscuity*; that is, heavy chains that were identical, or very closely related, were seen pairing with light chains of very a different sequence. This observation made it clear that the heavy- and light-chain pairings found in library-generated Fabs are not necessarily those encountered *in vivo*. All the specific Fabs were subsequently shown to compete with soluble CD4 for binding to gp120. This accords with the finding that more than 50% of the gp120 reactivity present in the donor serum may be inhibited by CD4. Moreover, a cocktail of 3 Fabs was able to inhibit more than 50% of gp120 serum reactivity from a selection of seropositive donors. These observations indicate that despite chain promiscuity, antibodies generated from combinatorial libraries are relevant to and reflective of the *in vivo* response.

Ultimately, the more interesting Fab antibodies are those that are not only able to neutralize viruses *in vitro* but protect against infection *in vivo*. To determine their ability to inhibit HIV-1 infection, Fabs were assessed in p24 ELISA and syncytia assays. Most Fab clones showed little or no neutralizing activity, but one group of closely sequence-related Fabs was able to neutralize 50% of the virus in both assays at a concentration of approximately 1 $\mu g\ mL^{-1}$. One of these Fab clones (termed *b*12) has been linked to Fc to generate whole IgG1 (see Section 3). In this form, it has been shown to be the most effective anti-HIV-1 antibody produced to date, combining potent neutralizing activity with broad strain cross-reactivity against a diverse panel of virus primary isolates. Significantly, passive administration of IgG1 b12 to macaques has been shown to completely protect against vaginal challenge of the simian-HIV hybrid ($SHIV_{162P4}$). In this experiment, the serum titer of IgG1 b12 required for sterilizing immunity was roughly 100 times greater than the 90% neutralization titer of the challenge virus. The X-ray crystal structure of whole IgG1 b12 has now been determined and is the first structure to be determined of an entire human IgG1 molecule (Fig. 5). The long CDR H3 loop is predicted to be important for its anti-HIV-1

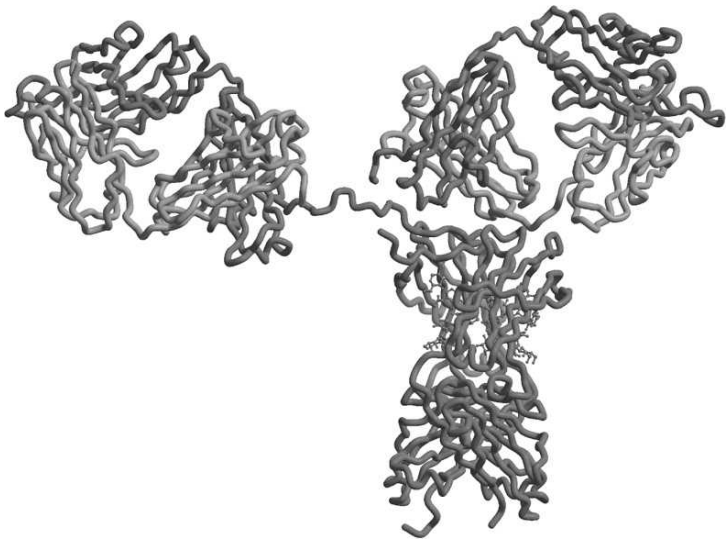

Fig. 5 Tube representation of the structure of the whole IgG1 b12, a broadly neutralizing human antibody against HIV-1. b12 was isolated from an Fab phage display library prepared from the bone marrow RNA of an asymptomatic HIV-1-seropositive individual. The structure was the first to be determined of an intact whole human IgG molecule. The light chains are shown in pink and the heavy chains in blue. Carbohydrate residues in the Fc portion of the molecule are also shown (see color plate p. xxii).

activity, and alanine-scanning mutagenesis of the CDR H3 loop of b12 supports this prediction.

Several other novel antibodies against HIV-1 have been selected by the use of phage display of which we will mention three. One antibody, Fab Z13, was selected using a synthetic peptide corresponding to the membrane-proximal region on the ectodomain of the transmembrane protein, gp41. This antibody and two others, 2F5 and 4E10, all bind to a similar region on gp41, and all of them are capable of cross-neutralizing primary isolates of HIV-1. Another antibody, Fab X5, was selected against a ternary complex of CCR5 (HIV-1 coreceptor), CD4, and gp120. Fab X5 has been shown to neutralize a wide range of primary isolates of HIV-1. Interestingly, the whole IgG X5 is actually poorer at neutralizing many viral isolates than its Fab counterpart, a property that has been attributed to steric constraints in accessing its epitope. A third antibody, scFv 4KG5, has been selected, which binds to a novel epitope on gp120 comprising the V1, V2, and V3 variable loops. The binding of 4KG5 to gp120 is inhibited by all anti-CD4 receptor binding site (CD4BS) antibodies tested ($n = 14$), and yet, its binding is moderately enhanced in the presence of the broadly neutralizing antibody b12 (described above). Thus, 4KG5 has helped distinguish, at the molecular level, b12 from other nonneutralizing anti-CD4BS antibodies.

Following the generation of the first recombinant Fabs against HIV-1, two more libraries were constructed from the bone marrow of additional HIV-1-positive asymptomatic donors. Analysis

of donor serum taken concomitantly with bone marrow samples indicated that these patients possessed measurable antibody titers against a plethora of different viruses. The libraries were then independently panned against antigens from the various pathogens to enrich for antigen-binding clones. Recombinant Fabs against HIV-1, RSV, herpes simplex virus (HSV) 1 and 2, varicella zoster virus (VZV), cytomegalovirus (CMV), and rubella were isolated from a single library, attesting to the antibody diversity captured during library construction. Essentially, existing antibody responses demonstrable at the serological level could be cloned and characterized at the molecular level.

Some of these Fab fragments were obtained by panning against lysates of virus-infected cells, rather than with recombinant or purified viral antigens. As a consequence, these experiments often generated antibodies against abundant, highly immunogenic antigens that do not elicit neutralizing antibodies in a natural immune response. To increase the probability of selecting neutralizing antibodies when purified antigen preparations are not available, a simple antigen-capture technique was developed. In this procedure, antigens known to contain important neutralizing epitopes (NE) are captured (typically from a lysate of virus-infected cells) onto a solid surface by an antibody specific for a nonneutralizing epitope (NNE) on the same antigen. Unbound material is then washed away, and panning is performed against the remaining captured antigen. In this way, only Fabs recognizing epitopes of the captured antigen (other than that occupied by the capturing antibody) are selected. Figure 6 gives an example taken from a capture-panning of the HSV glycoprotein D.

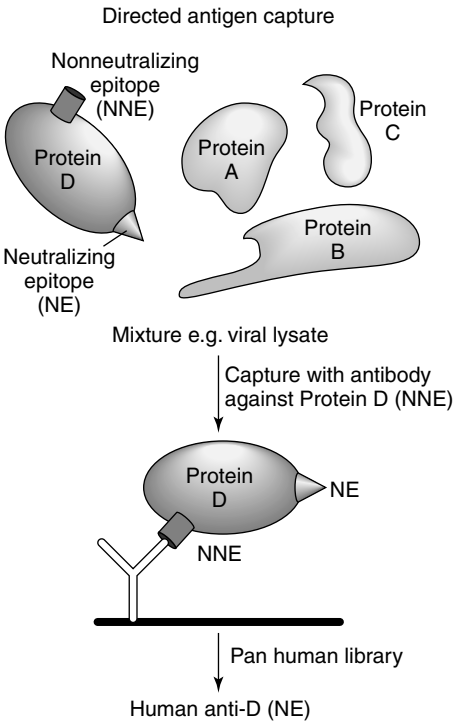

Fig. 6 Antigen capture prior to library panning. Library panning may be focused on a neutralizing epitope of a given antigen by first capturing the antigen, using a mouse antibody or a recombinant Fab that recognizes a nonneutralizing epitope. The method is advantageous when recombinant or purified forms of an antigen are not available.

Two recombinant antibodies with exceptional neutralizing properties have been isolated against RSV and HSV. The RSV-specific antibody was derived from a library prepared from a HIV-1-positive donor with high serum antibody titer to recombinant RSV surface glycoprotein FG. Panning the library against FG yielded the antibody RSV 19, which was shown to potently neutralize a diverse collection of field isolates. RSV 19 was later evaluated as an Fab for therapeutic efficacy in a murine model of RSV infection, and when administered

in the form of an aerosol directly into the lungs of infected mice at the time of peak viral replication, it was able to reduce the viral titer by a factor of 5000. These findings suggest that recombinant human monoclonal Fabs may prove useful in the therapy of RSV disease and other respiratory conditions in which virus replication occurs largely in the luminal lining of the respiratory tract.

The HSV-specific antibody was selected from a library constructed from a different HIV-1-positive donor whose serum had demonstrable antibody titers to HSV-1 and -2. Even though only one heavy-chain sequence was recovered by panning against both viruses, all the antibodies studied reacted well with HSV-1 and -2. Only one clone, Fab 8, which recognizes the HSV envelope glycoprotein D, was able to consistently neutralize the virus in a plaque-reduction assay. HSV Fab 8 has also been shown to both completely prevent plaque development in cell monolayers 72 h post infection, establishing that the Fab can neutralize after attachment of the virus to the host cell, and to protect mice against vaginal challenge with the virus.

The filoviruses, which cause hemorrhagic fever, are characterized by their extreme lethality (up to ~80% of those infected die) and have gained much media attention in recent years. Human Fab phage display libraries were constructed from the bone marrow from two donors who recovered from infection with Ebola virus during the 1995 outbreak in Kikwit, Democratic Republic of the Congo. Initially, only weakly binding Fabs could be selected by radiation-inactivated infected cell lysates. By contrast, soluble Ebola virus glycoprotein (SGP) and irradiated whole virions were used to select Fabs with high affinity to both SGP and nucleoprotein (NP). Of these antibodies, Fab KZ52, which binds to GP, had the greatest reactivity against live Ebola virus–infected Vero cells as shown by immunofluorescence. Fab KZ52 was engineered as a whole IgG1 molecule and, significantly, neutralized Ebola virus at 0.4 $\mu g\ mL^{-1}$ in a plaque reduction assay. IgG1 KZ52 was also shown to protect guinea pigs from lethal Ebola Zaire virus challenge. KZ52 protected at 25 $mg\ kg^{-1}$ was administered 1 h prior to (preexposure) or 1 h following (postexposure) virus challenge. Although sterilizing protection was not observed, plasma viremia was reduced by approximately three orders of magnitude. Whether human recombinant monoclonal antibodies against the filoviruses will be useful as prophylactic agents remains unknown.

Prion diseases such as scrapie and bovine spongiform encephalopathy (''mad cow disease'') are fatal disorders of protein conformation, which are characterized by progressive degeneration of the central nervous system. Mad cow disease has had enormous negative impact on the beef and cattle industry in the United Kingdom, and worldwide restrictions have been placed on the import of beef from the United Kingdom. The insidious transmissibility of prion diseases and the lack of a reliable and sensitive diagnostic test for prions has created a demand for highly sensitive agents to accurately diagnose prion protein in animals, animal products, and in humans. The molecular basis of prion propagation is generally believed to be that the pathogenic or ''scrapie'' form of the prion protein (PrP^{Sc}) acts as a template to convert the normal cellular prion protein (PrP^{C}) to the PrP^{Sc} form. Although the primary amino acid sequences of PrP^{C} and PrP^{Sc} are identical, numerous structural studies suggest that the conversion of PrP^{C} to PrP^{Sc} involves an extensive conformational change with substantial acquisition

of β-sheet content. Elicitation of antibodies against prion protein is difficult due to host tolerance of endogenous PrP^{C}. This problem was overcome by immunizing mice in which the *PrP* gene was ablated ($Prnp^{0/0}$), and antibodies were retrieved from phage display libraries prepared from the bone marrow and spleens of these mice. Fabs specific for both discontinuous and linear epitopes covering the majority of the murine prion molecule were isolated, most of which were cross-reactive with human PrP. Surprisingly, although the mice were immunized with infectious PrP fragment preparations, Fabs against only the cellular form of PrP were isolated (Fig. 7). The antibodies generated have given insight into the conformational changes associated with PrP. For example, several of the antibodies were used to show that PrP that is sparsely immobilized on a biosensor chip surface can undergo spontaneous rearrangement to a conformation similar to PrP^{Sc}. More importantly, one of the Fabs, D18, has been shown to bind tightly to cell-surface PrP^{C} and inhibit PrP^{Sc} formation in a dose-dependent manner. These results may eventually lead to the prevention or treatment of prion diseases by anti-PrP antibodies.

4.1.2 Antibodies against Tumor-associated Antigens

Combinatorial antibody libraries are being increasingly used in cancer research in which an increasing number of tumor-associated antigens are being identified as potential targets for disease intervention. The successes in treatment of certain cancers with monoclonal antibodies such as in the treatment of relapsed HER2 breast malignancy by Herceptin (Genentech), and B-cell follicular lymphoma by Rituximab (IDEC/Genentech), have set a precedence that could be followed by library-derived antibodies in the near future. There are many examples of phage display–selected antibodies against tumor-associated antigens, but we will mention only a few due to limitation of space. Of particular note are studies in which phage display–selected antibodies

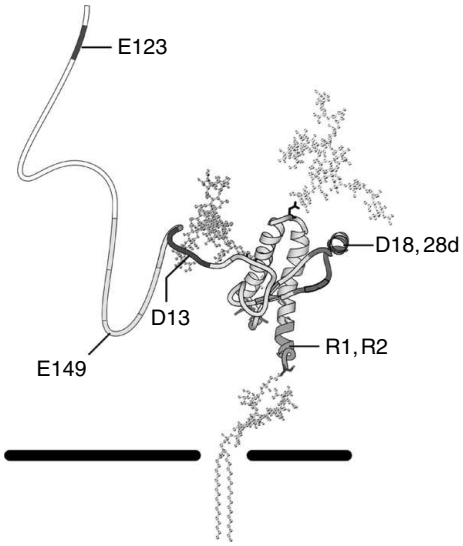

Fig. 7 Regions of prion protein (PrP) bound by individual antibodies selected from phage display libraries. Each antibody epitope has been assigned with a rectangle of different color as indicated on the figure. Beginning at the N-terminus, E123: purple; E149: grey; D13: blue; 3F4: yellow; 13A5: black line; D18 and 28d: red; R1 and R2: green. The cell membrane is shown as a black line at the bottom of the figure. The glycosylated side chains attached to Asn 181 and Asn197 are shown in orange and yellow respectively. The glycosyl phosphatidyl inositol protein (GPI) group anchoring PrP to the cell surface is shown in light blue. The antibody D18 has been shown to inhibit the formation of the infectious PrP^{Sc} form of the protein in a dose-dependent manner. [Adapted from Leclerc et al. (2003) *J. Mol. Biol.* **326**, 475–83.] (See color plate p. xxv.)

have given insight into the nature of the antibody response within tumors. For example, phage display libraries have been prepared from tumor-infiltrating B-cells revealing an oligoclonal antibody response against the intracellular autoantigen actin that becomes translocated to the cell surface upon apoptosis. Another group, using a similar approach, provides evidence for a bias toward intracellular antigens in the local antitumor immune response in a colorectal patient. Antibodies have also been selected against a number of gene products frequently found to be important in oncogenesis. An antibody library prepared from a colorectal cancer patient was used to isolate antibodies against the tumor suppressor p53. In another study, an antibody was selected against a stage-specific melanoma-associated antigen, and the antibody was used to identify a novel target, a 23 kDa glycoprotein, p23.

4.1.3 Intracellular Antibodies or "Intrabodies"

A relatively recent application of antibodies has been their use within the cell to modulate cellular function. Certain antibodies are able to bind to their target in the relatively oxidizing environment within the cytoplasm, and they can either act by inactivating a deleterious biochemical pathway or by initiating or enhancing a desirable one. In some cases, existing specificities can be engineered as scFvs specifically for intracellular expression, for example, by removing Cys residues and then selecting highly stable and functional variants using phage display. A number of experiments have demonstrated the ability of intrabodies to combat HIV-1 *in vitro*. Potential therapeutic applications of intrabodies hinge upon the potential of gene therapy, an area in which there has been a growing foundation of basic science and progress.

4.2 Antibodies in the Absence of Immunization

Isolating antibodies from an immune source has the advantage that the molecules will already have been selected by the host. However, there are many molecules of importance (e.g. self or highly conserved antigens) against which no high-affinity antibodies will be produced in the normal human host. Libraries prepared from "nonimmunized" or unimmunized sources provide the possibility of isolating these specificities. Moreover, given that libraries can be made approximating to the size of an animal's entire antibody repertoire, antibodies to a vast number of different antigens could become accessible from a single source.

4.2.1 Naive Libraries

Two main types of nonimmunized libraries have been described. In the first, "naive" antibody repertoires have been prepared using V genes from the IgD and IgM antibody classes. These antibody gene pools are less biased by the immune history of the host than those encoding IgG. Antibodies against a range of different molecules, including haptens and a number of self antigens, have been selected from such libraries. The antibodies have been shown to be highly specific, and, in some cases, of high (nM) affinity. More generally, however, they are of much lower affinity (1×10^5 to 1×10^6 M^{-1}) than those typically obtained from IgG libraries. In addition, from libraries of about 10^8 members, often only a small number of different clones of the desired specificity are selected. One of the most difficult

problems associated with this type of nonimmunized library is ensuring that the gene pool from which the library is made is truly naive. In fact, most V_H and V_L genes taken from IgM and light chain mRNA have already been biased in the host, precluding the selection of antibody against many antigens.

Nevertheless, some highly specific antibodies against diverse targets have been selected from nonimmune libraries. In one example, a nonimmunized library was screened against a diverse panel of antigens, and specific antibodies (scFv) were isolated in every case, including antibodies against botulinum neurotoxin, *Chlamydia trachomatis* elementary bodies, and the tumor marker Erb-B2; antibodies to the latter of which had dissociation constants below 1 nM. Another nonimmune library of $>10^{10}$ independent clones has been described from which has been isolated both cross-reactive and highly specific Fabs against the highly related glycoprotein hormones, human chorionic gonadotropin, human luteinizing hormone, and human follicle-stimulating hormone. Yet another nonimmune library was engineered using p9 display, and it performed comparably to many p3-displayed libraries.

4.2.2 **Semisynthetic Libraries**

Another source for nonimmunized libraries consists of antibodies that are encoded strictly by germ line genes. Such semisynthetic libraries are constructed from naturally occurring antibody genes in which some or all of the CDRs are composed of synthetic gene segments, and typically the CDR3 region of the heavy chain is composed of a randomized oligonucleotide sequence. A synthetic library has been described in which 49 V_H germ line genes were used as a starting point for library construction. These germ line heavy chains were given randomized CDR3 regions of five or eight residues and were combined with a single germ line lambda light chain gene. The library size of 2×10^7 clones represented only a fraction of the potential diversity in this system. However, this limitation must be considered in conjunction with the knowledge that immune systems themselves can represent only a fraction of the potential diversity at any one time, and that even germ line antibody genes are themselves biased by evolutionary pressures. To date, many synthetic antibody phage libraries have been described, some with considerable diversity (e.g. "Griffiths library," $\sim 6.5 \times 10^{10}$).

The importance of antigen recognition of CDR sequences, particularly the CDR3 of the heavy chain, makes them an ideal target for introducing segments of synthetic sequence to generate very large numbers of different specificities. Since naturally occurring heavy-chain CDR3 segments vary in length from 2 or 3 to 26 residues, the diversity that may be generated by randomization of this region alone is virtually limitless. In this sense, semisynthetic libraries may be considered to be more truly diverse and unbiased than those created from a naive source. However, although this aspect of library technology offers many possibilities, here too there are limits to diversity. For example, the complete randomization of 16 amino acids in a single heavy-chain CDR will alone require a library of more than 10^{20} clones to fully represent it. This figure is much greater than the transformation efficiency of *E. coli* (10^8–10^{10} clones per microgram of vector DNA). The probability of identifying desired specificities may, however, be increased by custom-designing semisynthetic libraries using

targeted mutagenesis and codon optimization. In addition, to mimic the affinity maturation seen in a secondary response *in vivo*, antibodies selected from both nonimmune and semisynthetic repertoires can be genetically manipulated *in vitro* to improve their affinity and/or modify their specificity. For example, it is possible to increase the affinity of these clones through the random mutagenesis of selected CDRs of the heavy chain followed by reselection against antigen. Additionally or alternatively, one can take a particular heavy or light chain and ''cross'' or reclone it into a light- or heavy-chain library respectively in the hope that it will pair with a more suitable partner. These strategies can often improve binding constants by more than two orders of magnitude, thus enabling high-affinity antibodies to be generated from naive sources.

Several companies are now in existence, which engineer and screen naive combinatorial antibody libraries that have been optimized to be very large and diverse. Fully human monoclonal antibodies have been selected against therapeutically relevant targets. In fact, Knoll Pharmaceuticals and the Cambridge Antibody Technologies Group have developed the first human antibody using phage libraries, which has been approved for human use and is marketed by Abbott Laboratories under the name Humira™ (http://www.fda.gov/ohrms/dockets/ac/03/briefing/3930B1_02_A-Abbott-Humira.pdf).

5 Summary

In the short time since their inception, combinatorial phage antibody libraries have been rapidly established as one of the most efficient routes to the generation of human monoclonal antibodies. Libraries prepared from immunized sources allow the selection of antibodies generated during a natural immune response. Moreover, the antibodies generated will normally be of high affinity following rounds of selection *in vitro*. Despite the scrambling of light and heavy-chain pairs inherent to library construction, antibodies selected from immune libraries have repeatedly been shown to be broadly reflective of the donor's serological reactivity. In addition, efficient selection procedures permit the isolation of antibodies occurring at very low frequencies in the library. Hence, library technology grants the investigator previously unavailable access to the human antibody response. Significantly, the problem of eliciting human antirodent responses, an enormous limitation to early therapeutic applications for rodent monoclonal antibodies, has been overcome as fully human antibody libraries are now readily available.

Libraries constructed from immune donors have already yielded a number of antibodies highly efficient in virus neutralization. Detailed information on the antibody response to infectious pathogens obtained through antibody libraries may be applied in the design and assessment of candidate vaccines as well as in elucidating the mechanisms by which viruses are neutralized by antibodies.

Unimmunized libraries, whether derived from naive repertoires or from synthetic antibody sequences, have almost unlimited potential to generate antibody specificities against any antigen. In some cases, these libraries have generated antibodies with affinities similar to those found in a secondary immune response *in vivo*. The resulting antibodies – having already been cloned at the

library-construction stage – are readily refined by mutagenesis. In combination with emerging array technologies, combinatorial antibody libraries are being used to identify binders for a multitude of novel targets and can be tested in high-throughput screens. These massive screening efforts are likely to yield new and improved diagnostics and therapeutics to further expand the already impressive role of antibodies in the clinic.

Keywords

Endogenous Substrates
Substrates for enzymatic (P450) reactions that are natural compounds synthesized within the organism harboring the enzyme.

Exogenous Substrates
Substrates for enzymatic (P450) reactions that are derived from the environment surrounding the organism harboring the enzyme.

Hemoprotein
A protein containing the prosthetic group, heme.

Monooxygenase
Enzyme that reduces O_2: one oxygen atom is used in substrate modification (often hydroxylation), while the other is used to form water.

Superfamily
A group of proteins that are evolutionarily related as determined by their primary amino acid sequence.

In the original issues of this Encyclopedia in 1996, there was the article (Volume 1) on cytochrome P450 monooxygenases. This new article follows the same format as that used previously. However, a great deal of interesting information on P450s has appeared in the last six to seven years. Accordingly, it is the goal of the authors to present the basic principles of the P450 system as outlined in the previous article, while at the same time taking advantage of new discoveries to provide more depth in understanding these fascinating enzymes.

Cytochrome P450 is the generic name applied to a large superfamily of hemoprotein, mixed-function oxidases (monooxygenases) that metabolize a structurally diverse group of exogenous and endogenous organic substrates. The name is derived from the prominent absorption band observed at 450 nm following reduction of the heme iron and its coordination with carbon monoxide. These enzymes are widely distributed among all biological kingdoms and they catalyze a reaction of the general nature

$$O_2 + \underset{\text{Biological reducing equivalents}}{\text{NAD(P)H}} + \underset{\text{Organic substrate}}{\text{AH}} \xrightarrow{\text{P450}} \underset{\text{Hydroxylated organic product}}{\text{AOH}} + H_2O + NAD(P)^+$$

In the case of exogenous substrates, this reaction is most frequently involved in an organism's effort to detoxify foreign compounds (xenobiotics) from the environment. In the case of endogenous substrates, the reaction is generally involved in the production of biologically more active compounds (viz. steroid hormones) from less active compounds (viz. cholesterol).

1 Characteristics of P450s

In 1962, Ryo Sato and Tsuneo Omura characterized an unusual pigment in a subcellular fraction of rabbit liver, the endoplasmic reticulum, which showed an intense absorbance band at 450 nm upon reduction and coordination with carbon monoxide. They tentatively named the material ''pigment 450 nm'' or ''cytochrome P450.'' The latter name

stuck even though cytochromes P450, being enzymes, do not fit the true definition of cytochromes. Subsequently, the pigment in question was shown to contain protoheme, the same prosthetic group found associated with many other hemoproteins, most notably hemoglobin and myoglobin. Hemoglobin and myoglobin also show an intense absorbance upon reduction and binding to CO, but with these proteins the maximum is at 420 nm. Iron has six coordination positions: four coordination positions in protoheme are occupied by the pyrrole nitrogens; in hemoglobin and myoglobin, the fifth coordination position is provided by the imidazole group of the proximal histidine; and the sixth position is available to bind gaseous ligands such as O_2 or CO. It is now apparent that in P450s, the fifth coordination position is provided by a thiolate group from the amino acid cysteine. Although the Nomenclature Committee of the International Union of Biochemistry suggests the name ''heme-thiolate protein'' rather than ''cytochrome P450,'' common usage in the field is simply P450, dropping the ''cytochrome.''

Shortly after Sato and Omura tagged this hemoprotein as cytochrome P450, Ronald Estabrook, Otto Rosenthal, and David Cooper at the University of Pennsylvania assigned a function to a cytochrome P450 in the endoplasmic reticulum of the adrenal cortex by demonstrating with CO inhibition and photochemical action spectroscopy its ability to hydroxylate progesterone at C-21. We now know that there are many different P450s and that they catalyze the general reaction type shown above.

Returning to our analogy with hemoglobin, we recognize that a fundamental difference between P450 and hemoglobin is that hemoglobin binds O_2 reversibly and transports it unchanged, while P450 reduces O_2, one atom of oxygen being inserted into the substrate and the other used for the formation of water. The redox potentials of these two hemoproteins are quite different, that of P450 being -300 mV or lower, while that of hemoglobin is $+110$ mV. Presumably, the electron-donating capacity of the thiolate ligand can facilitate the reduction of O_2, making P450s potent monooxygenases. Not all heme-thiolate proteins are P450s, but we will find that P450s consist of a very large number of proteins (over 2,400 identified to date) found in plants, bacteria, birds, fishes, insects, mammals, and probably all other forms of life.

For the heme iron to reduce oxygen, cytochrome P450 must receive electrons from reduced pyridine nucleotides (either NADH or NADPH) via an electron transport system. In bacteria, P450s are soluble proteins; in plants, insects, and animals, they reside as integral members of subcellular membranes. Virtually all soluble bacterial P450s, as well as those forms localized in mitochondrial membranes of eukaryotes, receive electrons via the following pathway:

$$\text{NADPH(NADH)} \longrightarrow \underset{\text{(FAD – containing)}}{\text{ferredoxin reductase}} \longrightarrow \underset{\text{(often 2Fe-2S)}}{\text{ferredoxin}} \longrightarrow \text{P450}$$

Electrons are transferred to the P450 one at a time from the ferredoxin. In mitochondria, P450s are localized to the inner mitochondrial membrane, with ferredoxin reductase and ferredoxin residing as soluble proteins in the matrix. In eukaryotes, the majority of P450s are localized in the endoplasmic reticulum as integral membrane proteins. Reducing equivalents are transferred to these P450s via a microsomal flavoprotein quite distinct from

ferredoxin reductase:

$$\text{NADPH} \longrightarrow \underset{\text{(FAD + FMN containing)}}{\text{NADPH P450 reductase}} \longrightarrow \text{P450}$$

where FAD is flavin adenine dinucleotide and FMN is flavin mononucleotide. A small number of variations in the reductase systems do exist amongst the P450 superfamily. In at least one case, a soluble bacterial P450 utilizes the microsomal type of reductase system that is attached to the C-terminus of the P450 domain to form a fusion protein. Another type of P450 fusion protein having a ferredoxin domain attached to the P450 domain is also found in bacteria. In another example found in fungi, reduced pyridine nucleotide interacts directly with the P450.

In summary then, P450s are protoheme-containing, mixed-function oxidases in which a cysteine thiolate ligand coordinates the polypeptide chain to the heme iron. In bacteria, these proteins are soluble, while in higher life-forms they are integral membrane proteins. Virtually all P450s require additional proteins to transfer electrons from reduced pyridine nucleotides to their heme iron.

2 P450 Functions

P450s metabolize a wide range of both endogenous and exogenous (foreign from the environment) compounds. These compounds generally are lipophilic, and it is predicted that the P450 superfamily can metabolize more than 10,000 known compounds. Endogenous substrates include steroids, fatty acids, prostaglandins, leukotrienes, bile acids, and biogenic amines, while exogenous substrates include environmental pollutants and pharmaceuticals. P450s catalyze the oxidative, peroxidative, and reductive metabolism of such compounds. In the broadest sense then, we can group P450s into two classes: those that metabolize endogenous compounds and those that metabolize exogenous substrates (Table 1). The general catalytic mechanism for oxygenation by P450s of both types of substrate can be represented by the cycle shown in Fig. 1. Binding of substrate in the P450 active site has been shown in some cases to raise the redox potential of the heme iron to about −180 mV, making it more susceptible to reduction by NADPH.

In animals, the forms involved in endogenous substrate metabolism tend to be localized in specific functional sites such as steroidogenic tissues (adrenal, gonads, placenta) or a specific organ (kidney, liver) in which they participate in key endogenous pathways such as steroid hormone biosynthesis (mineralocorticoids, glucocorticoids, sex hormones), bile acid biosynthesis, vitamin D_3 activation and inactivation, and synthesis of key metabolites from arachidonic acid. These reactions lead to the production of regulators of many biological processes such as reproduction and vascular activity, to name only two. Other potential roles for P450s include biosynthesis of neurosteroids and activation or inactivation of important compounds for growth and development including derivatives of vitamin A. Certain P450-dependent endogenous functions such as cholesterol biosynthesis are widely distributed. Cholesterol biosynthesis is important in most, if not all, animal cells for membrane biogenesis and is dependent on lanosterol 14α-demethylase cytochrome P450. A key developmental role for P450-dependent activities is

the requirement for testosterone at the correct time during fetal life for the appearance of the male phenotype. Without timely testosterone production, the 46,XY male karyotype displays female sex characteristics, and two different P450s (one mitochondrial and one microsomal) are required for testosterone biosynthesis from cholesterol. In the male songbird, testosterone produced in the testis crosses the blood–brain barrier, where it is converted to estrogen by the aromatase cytochrome P450 in the brain, which activates the formation of the song center in the brain.

Inherited genetic diseases are known to be associated with mutations in the P450-encoding genes involved in endogenous substrate metabolism. For example, the group of diseases known as congenital adrenal hyperplasia results from defects in steroid hormone biosynthesis in the gonads and adrenal. Depending on the specific *P450* gene affected, alterations in these pathways lead to changes in mineralocorticoid, glucocorticoids, or sex hormone levels. Another P450-dependent pathway subject to genetic defects is bile acid biosynthesis. Recently, a mutation in a fatty acid hydroxylase P450 expressed in tubules in the kidneys has been found to be associated with human hypertension. Aromatase P450 is required for estrogen biosynthesis and, in addition to expression in the ovaries, it is found in adipose (fat) tissue, in which it may be a key locus in breast cancer. Thus, members of the class of P450s involved in endogenous substrate metabolism play important roles in development and homeostasis and are the loci for a number of disease states in humans.

Forms of P450 involved in exogenous substrate metabolism are generally more widely distributed and have broader substrate specificities than forms involved in endogenous substrate metabolism. Exogenous substrate metabolism is found in every organ including the skin, while the highest concentration and largest number of exogenous substrate–metabolizing P450s is in the liver. Some forms in this class are widely distributed, such as that which metabolizes polycyclic aromatic hydrocarbons (P4501A1 – this nomenclature is defined in the next section), which can be found in almost every cell type. Others are present in only a limited number of cells such as the olfactory epithelium.

In bacteria, P450-dependent xenobiotic (foreign compound) metabolism can involve compounds that serve as important carbon sources for these organisms. A particular strain of *Pseudomonas putida* grows on camphor following its metabolism via several enzymatic steps, including one catalyzed by the soluble cytochrome P450cam. In insects, P450-dependent xenobiotic metabolism can provide protection against plant toxins produced to ward off pests. The larvae of the black swallowtail butterfly are able to feed on carrot and parsley plants because they can rapidly induce a particular P450 that metabolizes the xanthotoxin produced by the plants. Many other insects cannot generate such a defense in the warfare between plants and insects and thus cannot feed on naturally protected plants. Taxol, an important anticancer agent that disrupts microtubule formation, is produced by the Pacific yew tree via a P450-dependent pathway as a defense against pests. Animals including humans contain a broad spectrum of different P450s capable of biotransforming pollutants and drugs. These transformations (generalized in Table 1) involve countless drugs, chemical carcinogens, and environmental contaminants. From an evolutionary point of view, it is interesting to consider how these forms

arose. Our modern chemical environment is less than 200 years old. Nevertheless, forms such as P4501A1 are found in fishes and all mammals. This P450 metabolizes polycyclic aromatic hydrocarbons, which can arise from burning organic matter. Perhaps such forms were first produced during volcanic eras and have persisted to present times.

Much of the P450-dependent xenobiotic metabolism serves the purpose of detoxification. Hydroxylated products are more soluble than the original substrates and also serve as good substrates for phase II detoxification enzymes, which conjugate these products for easier elimination. Obviously, this ability is beneficial to humans, just as detoxifying xanthotoxin is beneficial to the black swallowtail butterfly larvae. In certain cases, however, products produced by P450 metabolism can be more toxic than the substrate. For example, benzo(a)pyrine, a polycyclic aromatic hydrocarbon in tobacco smoke that also arises from charbroiling meat, is converted by P450-dependent biotransformation into a product that is carcinogenic and may play a key role in lung cancer. Thus, in certain instances, products of P450 biotransformation can be mutagenic or carcinogenic.

The pharmaceutical industry is particularly interested in the roles P450s play in drug metabolism. This metabolism obviously contributes to the efficacy of pharmaceuticals. In drug metabolism studies using laboratory animals, inbred strains are generally used in which all individuals contain fairly constant levels of different forms of drug-metabolizing P450s. Humans are outbred and show considerable individual variation in drug metabolism. Each individual can be considered to have a unique drug-metabolizing profile in part because of the person's individual P450 pattern, which is dependent on genetic (sex, age) and environmental (nutrition, exposure) factors. The human genome has revealed genomic evidence for 57 P450s to date, a mixture of forms metabolizing endogenous and exogenous substrates. Of this latter group, six found in human liver are primary P450s used to study P450 metabolism of potential pharmaceuticals. In some cases, different forms of P450 metabolize the same chemical substrate by different reactions, leading to varied patterns of products from the same drug. Thus, individual variation in the levels of different P450s can significantly affect drug metabolism, particularly in instances of combined drug therapy. Genetic contributions to individual variations (drug metabolism polymorphisms) exist within the human population as a result of variations in the levels of specific forms of P450 or mutations within specific enzymes. Thus, certain individuals, classed as poor metabolizers for specific drugs, do not clear these drugs as efficiently as the general population and experience side effects reminiscent of drug overdose. A goal of research in drug metabolism is to develop noninvasive screening procedures that will permit estimation of individual P450 profiles. Thus, individual treatment regimens could be prescribed providing both health and economic benefits to patients.

While the classification of P450s into two groups as used here is helpful, ancestral P450s probably have existed for more than 3.5 billion years. This longevity suggests that the drug-metabolizing forms of P450 could play important roles in regulating key endogenous compounds used in growth, development, and homeostasis. In most cases, no biological connection between members of the exogenous substrate–metabolizing class and specific endogenous substrates (e.g. retinoids) has

yet been made. However, because drug-metabolizing P450s have a broad substrate specificity, it is clear that, *in vitro*, these P450s can metabolize various endogenous compounds. Thus, it will not be surprising to see the distinction between these two classes of P450 become less sharp in the future.

3 How Many P450s Are There?

The P450 superfamily is very large, having members in most if not all life-forms. In 1996, only 400 CYPs were known and now the P450 superfamily contains more than 2400 enzymes. The majority of these have been identified in genomic sequences and for the vast majority, the function is unknown. Classification of members of the superfamily based on function has not been possible, originally because enzymes from the same superfamily in different species have different activities and now because we have far too many genes with unknown activities. Rather, a systematic classification for P450s has been developed on the basis of amino acid sequence (http://drnelson.utmem.edu/cytochrome.P450.html). Before development of this classification by Dan Nebert and David Nelson, the field was in disarray because individual investigators selected names for the different P450s, and in cases in which discovery occurred in two laboratories at about the same time, there were two names for the same CYP. The nomenclature involves a number that identifies the gene family, a letter that identifies the subfamily, and another number that identifies the member of the subfamily. CYP2C23 indicates gene family 2, subfamily C of gene family 2, and member 23 of subfamily C of gene family 2. The subfamily member designation is sequential based on order of discovery. CYP2C23 and CYP2C24 are rat P450s, while CYP2C25 is from the Syrian hamster. Gene family members have about 40% amino acid sequence identity or greater, while subfamilies have about 55% amino acid identity or greater. Certain gene families that have very restricted enzymatic activity and are found to have the same function in different organisms do not have subfamilies. CYP51 (sterol 14α-demethylase) is an example because it is involved in sterol biosynthesis in many organisms in which it removes the 14α-methyl group from the cyclized sterol ring. Another such example is CYP17 (17α-hydroxylase/17,20-lyase) found in the gonads of animals, birds, and fish serving an identical role in androgen biosynthesis. However, the P450s in the CYP2C subfamily generally have different substrate specificities from those in the CYP2B subfamily. It would not even be surprising to learn that CYP2C23 and CYP2C24 have different substrate specificities. Sometimes, a single amino acid change can profoundly change the specificity of a P450. In the mouse, the Cyp2A subfamily (Phe209 $\rightarrow$ Leu) changes the specificity of mouse coumarin hydroxylase (Cyp2A5) to steroid 15α-hydroxylase (Cyp2a4). For mouse P450s Cyp is used, while for P450s in all other species the designation CYP is used.

CYP51 is expressed in all kingdoms of life, and the approximately 50 known CYP51 sequences contain 40 conserved amino acids. Obviously, sterol 14α-demethylation is a highly conserved enzymatic activity. Another highly conserved enzymatic activity is ω-hydroxylation of fatty acids. However, in this case different gene families are involved in different phyla. There is not enough amino acid conservation between different

fatty acid hydroxylases to catalog them together in the same gene family. Perhaps this difference between sterol 14α-demethylation and fatty acid ω-hydroxylation is because three successive monooxygenation steps are required for 14α-demethylation and only one for fatty acid hydroxylation. Only three amino acid residues are conserved in all P450s, the cysteine that provides the thiolate ligand for the heme iron and the EXXR sequence that forms a charge pair in the K-helix of P450s. The number of P450s are very different from organism to organism and Table 2 provides selected examples that emphasize this point.

As indicated earlier, knowing the sequence of a P450 does not necessarily provide information on its function. A variety of different heterologous expression systems including bacteria, yeast, insect cells, and animal cells have been applied to P450 research. Thus, as new P450s are identified by cloning, they can be overexpressed and their enzymatic properties examined with a variety of potential substrates. Even following such characterization, however, it is not possible to know specific P450 function with certainty in the absence of biological data, including tissue localization and physiological regulation of activity. Directed approaches to identify rare P450s are difficult. Universal probes do not exist for P450s, either nucleotide or antibodies. Use of subfamily-specific PCR primers does permit identification of new P450s within a limited subset. P450s contain approximately 500 amino acids, of which fewer than 10 are highly conserved, several of these being located near the heme-binding cysteine. In studies aimed at cloning P450 genes responsible for flower color, degenerate PCR primers complementary to sequences in the heme binding region were very effective in identifying a number of different P450 forms.

4 P450 Structure

In the 1996 article, it was reported that four soluble bacterial P450 structures were known. This number has grown to at least nine. In addition, we now know the structure of a soluble fungal P450, and most

Tab. 2 Expression of P450s in different organisms.

Organism	*Number of CYPs*
Human	57
Mouse	60

Mycobacterium leprae	1
Streptomyces coelicolor	18
Streptomyces avermitilus	33

exciting, the structures of mammalian, membrane-bound CYPs are becoming available. The first is a rabbit microsomal steroid hydroxylase, CYP2C5, and a commercial firm has reported structure determination of two human hepatic CYPs (2C9 and 3A4). Because eukaryotic CYPs are integral membrane proteins and are consequently more hydrophobic, they are more difficult to crystallize. However, that is true of proteins in general where more than 2,000 structures of soluble proteins are available, yet only about 50 membrane protein structures have been solved. The recent success in structure determination of eukaryotic P450s has required modification by mutagenesis to generate less hydrophobic molecules. We can expect additional structures of human P450s to appear in the near future.

Generally speaking, there is little sequence conservation between *CYP* gene families. However, the CYP structures all look the same from a distance, assuming what is now called the *P450 fold*. Closer analysis reveals, however, subtle but important differences. More than 10 years ago, Gotoh described in the CYP2 family six ''substrate recognition sequences'' (SRS). These regions are predicted to interact with the substrate and are hypervariable between gene families but are more conserved within P450s that carry out similar or the same reactions. Having considerable structural information on P450s, we now think of these regions in terms of secondary structural elements. SRS1 is generally found in the region of B′-(or B)helix and BC loop, SRS2 in the C-terminal region of the F-helix, SRS3 in the N-terminal region of G-helix, SRS4 in the I-helix, SRS5 in $\beta 1-4$, and SRS6 in $\beta 4-2$. The lengths of these secondary structural elements vary between P450 families to accommodate substrates of different shape, size, and polarity. From structural studies, we know that the active site in P450s is sequestered inside the protein molecule, and it is not clear at present how the substrate gains access to the enzyme's active site. Only in two cases has the structure of the same CYP plus and minus substrate been determined – the bacterial enzymes P450cam and P450BMP. In the case of P450BMP (CYP102A1), there is a channel (substrate access channel) that connects the surface of the molecule and the buried active site, which is open in the substrate-free form of the enzyme. Binding of the substrate causes significant conformational changes and results in a closure of the substrate access channel. This is in contrast to P450cam (CYP101), in which there is no obvious route to the active site and substrate binding is accompanied by only minor conformational changes.

P450s in the endoplasmic reticulum have a very hydrophobic amino-terminal region, which serves as a signal anchor sequence. All such P450s are inserted co-translationally into the endoplasmic reticulum membrane by the signal recognition particle pathway, and this amino-terminal anchor participates both in association of the P450 with the membrane and in directing the proper folding pathway for the protein. However, removal of this hydrophobic tail from the primary sequence of the P450 does not generally lead to synthesis of a soluble P450. Rather, such truncated P450s are still found to be associated with the membrane, indicating that other hydrophobic stretches in the P450 molecule participate in membrane association. Even P450s in the mitochondrion do not have discernible hydrophobic signal anchors. They, however, have amino-terminal precursor extensions that are removed proteolytically as the unfolded P450 is taken up

and inserted into the mitochondrial membrane before final folding occurs. There is no sequence homology of this extension between different mitochondrial P450s and its length varies significantly from one protein to another. Like other precursor sequences, however, mitochondrial P450 precursor segments contain charged amino acids. All membrane-bound P450s are proposed to have a similar mode of association with the membrane via a large hydrophilic domain anchored to the lipid bilayer through several noncontiguous portions of the polypeptide chain, with some of the membrane-interacting areas being common to both mitochondrial and microsomal P450s. It has also been suggested that in membrane-bound P450s the substrate may enter directly from the lipid bilayer, thus providing a rationale as to how hydrophobic substrates can avoid traveling through the aqueous cytosol.

Other than addition of protoheme, posttranslational modification is not a frequent event in P450s. There have been reports that phosphorylation is important in modifying the function of specific forms of P450, but this has not been firmly established. Glycosylation of aromatase cytochrome P450 is known to occur, although this modification apparently has no effect on the activity of the enzyme. Glycosylation of other P450s is not common. Heme binding remains the one posttranslational event occurring in all P450s. How it occurs, however, is not at all understood. Since the last step of heme biosynthesis (iron insertion into protoporphyrin IX) occurs in the mitochondrion, mitochondrial P450s might find heme quite readily in the matrix. How heme gets to the endoplasmic reticulum for insertion into P450s and other heme proteins is a mystery.

5 Regulation of P450 Activities

While certain P450-dependent activities, such as the lanosterol 14α-demethylase step in cholesterol biosynthesis and that of 27-hydroxylase in bile acid biosynthesis, have important constitutive regulatory components, other P450 activities are regulated by signal transduction pathways. Much of this regulation is at the transcriptional level. For example, peptide hormones from the anterior pituitary regulate transcription of P450s involved in steroid hormone biosynthesis. Adrenocorticotropin (ACTH), via cAMP-dependent pathways, controls the transcription of genes in the adrenal cortex, encoding both mitochondrial and microsomal P450s in the steroid hormone biosynthetic pathway, as well as related proteins such as ferredoxin. ACTH also controls the availability of substrate (cholesterol) in the inner mitochondrial membrane, thereby having the dual effect of regulating enzyme levels and substrate availability. As another example, parathyroid hormone regulates P450-dependent vitamin D_3 metabolism via cAMP, presumably at the transcriptional level.

When considering regulation of P450 activities, there are four different regulatory components to be evaluated: development, tissue-specific, constitutive, and inducible. Not all P450s are inducible, but the other three factors of this multifactorial regulatory scheme probably apply to all eukaryotic P450s. We do not yet have a good view of the multifactorial regulation of most P450 enzymes, the steroid hydroxylases being the best understood. In addition to peptide hormone–dependent regulation through cAMP, developmental/tissue-specific regulation is dependent on an orphan nuclear

receptor transcription factor known as SF-1, which also plays a key role in organogenesis of the adrenal and gonads. Constitutive regulation of steroid hydroxylase levels is mediated by growth factors and cytokines.

Many forms of P450 are induced by substrates. Camphor, the substrate for P450cam, regulates the level of this P450 and other enzymes involved in camphor metabolism. It has been noted that xanthotoxin produced by carrot and parsley plants induces P450 levels in certain butterfly larvae, permitting them to metabolize this toxin and therefore feed on the plants. Drugs and pollutants that serve as substrates for many P450s can function to induce the levels of the specific forms that detoxify them. In a well-studied example, polycyclic aromatic hydrocarbons, some of which are substrates, induce the level of P4501A1 through a specific receptor that binds a unique DNA sequence associated with CYP1A1 when the ligand (polycyclic aromatic hydrocarbon) is bound. The same regulatory process for P4501A1 exists in fish and all animals, raising the possibility that there is an endogenous ligand for this receptor. Polyacrylic aromatic hydrocarbons derived from burning organic matter must have been in the environment for a very long time. Modern polycyclics such as dioxin are potent inducers of this P450 by this receptor-mediated mechanism, which probably has existed for millions of years. Therefore, the question remains as to whether P4501A1 might be regulated by a naturally occurring compound that might also be a substrate for this P450. Barbiturates such as phenobarbital enhance levels of certain forms of drug-metabolizing P450s, while peroxisome proliferators such as clofibrate induce levels of yet other P450s. Pharmaceutical companies not only need to know what forms of P450 metabolize potential new drugs and what the resultant metabolites are but they also need to be aware of the forms of P450 that are induced by such compounds, because alteration in the P450 profile by induction can alter the pattern of drug metabolism. Overall, the levels of P450s in all organisms are regulated by environmental conditions. In higher organisms, developmental, tissue-specific, and endogenous systems also contribute to the existing levels of P450s. Since there is little post-translational modification of P450s that influences enzymatic activity, levels of the monooxygenases themselves must be key in controlling activity. Transcription is a very important player in this aspect of P450 function, although translation that has not been studied as extensively as transcription may also be important.

6 Future Directions

This section, in 1996, began with three questions that were considered to be particularly important from the standpoint of the pharmaceutical industry.

- How many human forms of P450 are there?
  From the human genome we now know that there appear to be 57 human CYPs.
- What are the overlapping substrate specificities of the major P450 forms to a variety of drugs?
  Of course, this is a question that will forever be an ongoing one because of the development of new drugs. However, we now know the number of CYPs and, in most cases, they can be expressed in heterologous systems providing sufficient enzyme for analysis of substrate specificity. Thus, the methods are clearly

available to test the ability of different human CYPs to metabolize a common substrate. Most often, this analysis will not include all 57 human CYPs but rather the 6 major drug-metabolizing forms in human liver (3A4, 2C9, 2C19, 2E1, 2A1, 2D6).

- How are the major human forms of P450 regulated?
  This has been a rapidly growing area of research over the past seven years. Particularly, discovery of transcription factors such as PXR, CAR, LXR, along with further understanding of the mechanism by which AhR functions to induce CYPs through polycyclic aromatic hydrocarbons, have begun to bring rationale answers to this question.

The other two questions in 1996 are

- What genetic and environmental factors control the individual levels of these enzymes, and can noninvasive screening tests be developed to determine an individual's P450 profile?
- Can designer drugs be developed for targeting specific P450 active sites?

We do not have clear answers to these at this time. However, development of microarray technologies and methods for solving the structures of human CYPs should assure some answers to these questions by the time the next volume is written. Many of the same questions are also being asked by the agricultural industry in its search for new herbicides and pesticides.

The role of the P450 superfamily in growth and development will be one of the major issues addressed in academic laboratories during the next decade, along with the elucidation of the three-dimensional structure of eukaryotic P450s and the biochemistry of the regulation of *P450* gene expression. In addition, questions that remain to be answered focus on substrate accessibility and binding, particularly to P450s of the endoplasmic reticulum, and association of these P450s with limiting amounts of P450 reductase in the membrane.

One of the major thrusts during this decade will be in application of the unique chemistry catalyzed by P450s for commercial purposes. The recent success in producing cortisol by insertion of a mammalian P450–dependent metabolic pathway in yeast is very exciting and opens the door to other future efforts. At the same time, the solution of the *Streptomyces coelicolor* genome demonstrating the presence of 18 *CYP* genes opens the way to modification of P450s leading to novel secondary metabolites. The opportunity will soon exist to make novel and more potent antibiotics by modifying specific *CYP* gene(s) in particular streptomycetes. The use of microorganisms for expression of specific forms of P450 may also prove important in pollutant control. Organisms engineered to metabolize compounds such as polycyclic aromatic hydrocarbons may be very important in protecting the environment. In the context of fine chemical or pharmaceutical synthesis and in pollution control, the ability to change the catalytic activity of a specific P450 could be particularly useful. The realization of designer P450s engineered to catalyze specific activities may not be far in the future, since solution of the three-dimensional structure of eukaryotic P450s would seem to be a lesser obstacle than before.

Finally, transgenic plants expressing P450s that provide protection against insects and herbicides are presently being tested. Also, transgenic plants are being developed to modify flower color and for the production of commercially important

oils. Efforts to produce blue roses by modifying the P450 profile are under way. The flavor spearmint is produced by a plant much less susceptible to disease than that producing peppermint. Knocking out one *P450* gene and inserting another should in principle generate peppermint flavor in the spearmint plant, thereby lowering the cost of peppermint flavorings.

Many fundamental details concerning P450 systems at the biochemical and cell biology levels remain to be elucidated, and we can anticipate continued vigorous activity in these areas. The discovery of new forms of P450, particularly in plants and insects, will proceed at a rapid pace. Finally, applications of P450-catalyzed chemistry to commercial projects, including synthesis of chemicals, pollution control, and agriculture, are becoming important directions of this area of investigation.

Keywords

Cytokine
One of a class of inducible biologically active proteins that exercise specific, receptor-mediated effects in target cells or in the cytokine-producing cells themselves.

Interleukin
One of several different cytokines acting between leukocytes and other cell types, which has a variety of stimulatory activities that regulate immune, inflammatory, and hematopoietic responses.

Hematopoietin
One of a subgroup of interleukins having an α-helical bundle structure.

Hematopoietin Receptor
One of a class of structurally related cell surface receptors for the hematopoietin subgroup of interleukins.

Hematopoiesis
The process of populating and replacing circulating erythrocytes and leukocytes from stem cells contained within the bone marrow.

Macrophage
Phagocytic leukocyte found in various tissues, which is important in nonspecific cellular immunity and antigen presentation, and which is a major producer of and responder to interleukins.

T lymphocyte (T cell)
A type of white blood cell capable of responding to foreign antigens and thus of mediating cellular immunity, which it does by secreting a variety of interleukins and other cytokines to activate leukocytes and other cells.

Homolog
A structurally related interleukin molecule whose activity is mediated by a receptor that is common to all homologs within an interleukin family.

Paralog
A structurally related interleukin molecule whose activity is mediated by a receptor distinct from those of other paralogs within an interleukin family.

The harmonious regulation of vital physiological processes, for example, replenishment of mature blood cells from bone marrow stem cells, termed *hematopoiesis*, and the activation of defense mechanisms against pathological microbes and injury has been shown to depend on the production and action of a variety of secreted biologically active proteins, collectively known as cytokines. Central among cytokines is a class of mediators, largely involved in the regulation of immune, inflammatory, and hematopoietic functions, designated interleukins primarily on the basis that interleukins are produced mainly by leukocytes and act locally on other leukocytes in surrounding tissues. Each interleukin, of which there are now 29 designated ones, exercises a spectrum of biological activities via specific cell surface receptors. Overlaps of biological activities have been found to be common among different interleukins and to result in many cases from the sharing of receptor components. On binding their cognate interleukins, receptors activate intracellular signaling pathways leading to the transcription of nuclear genes and expression of proteins necessary to commit the cell to a number of contingent events and responses according to the particular interleukin bound and cell type. Interleukins, however, probably rarely act alone and *in vivo* form complex interactive networks both among themselves and with other cytokines. Such complicated intercellular communications systems have made it difficult to precisely define the biological roles of interleukins in health and disease. In certain diseases, for example, cancer, some exogenously administered interleukins induce beneficial responses, but it has

rarely been possible to dissociate their desirable pharmacological activities from their undesirable pharmacological activities, which often give rise to severe side effects. In fact, many disease symptoms, for example, fever, hypotensive shock, have been demonstrated to be strongly associated with the presence of endogenously produced interleukins, and this is leading to clinical evaluation of several interleukin antagonists in both acute and chronic diseases.

1 Background and Historical Perspective

From the beginning of the twentieth century, there has been a growing realization that many of the biological processes in multicellular organisms are regulated by extracellular factors. Together such factors constitute an elaborate, interactive communication system that governs the cellular and physiological responses at several levels. In particular, the immune and neuroendocrine systems of higher animals, such as mammals, are subject to regulation by secreted factors that can act both locally (paracrine action) and at a distance (endocrine action) on cells bearing cognate receptors. The word ''cytokine'' was coined in 1974 by Dr Cohen to describe any soluble factor produced by both lymphoid and nonlymphoid cells that exercise specific effects in its target cells. Since then, the definition of cytokine has become restricted to nonendocrine, biologically active, protein mediators involved in (1) cell proliferation and thus tissue development and repair and (2) cellular function, which is required for the maintenance of homeostatic and defense mechanisms. Cytokines may be perceived to be analogous to polypeptide hormones except, in contrast to hormones, cytokines mainly act locally rather than at a distance. However, in many respects the distinction between cytokines and hormones is blurred.

In today's classification, interferons, interleukins, colony stimulating factors, and polypeptide growth factors are considered to belong to the cytokine superfamily. The word ''interleukin'' was coined in 1979 at the 2nd International Lymphokine Workshop in Ermatingen, Switzerland (quite possibly interleukin was born from a corruption of Interlaken, another town in Switzerland!), to apply to soluble mediators produced by activated T lymphocytes that acted in a paracrine fashion on ''responder'' lymphocytes. However, the definition of interleukin was quickly widened to include soluble mediators produced by a wide variety of cell types that acted primarily on lymphocytes and other cell types within the immune system. Regrettably, prior designation of some of the earlier characterized cytokines, for example, interferon gamma (IFNγ), has effectively excluded them from the interleukin family to which they truly belong, and the inclusion/exclusion of newly discovered cytokines to the interleukin family has often been fairly arbitrary.

Historically, the biological activities that are now attributed to interleukins were first uncovered as early as the 1940s. Then, for example, a fever-inducing substance isolated from ''neutrophils'' was called *granulocyte pyrogen* (GP); it had similar properties to endogenous pyrogen (EP), a substance isolated from the blood of rabbits made febrile by the injection of

bacteria. Since then and particularly in the late 1960s and early 1970s, many other biological activities have been defined, being originally ascribed to poorly characterized, soluble factors. Thus, lymphocyte activating factor (LAF) was the name given by immunologists to a macrophage-derived substance that enhanced mitogen-driven lymphocyte proliferation. A substance secreted by such mitogen (lectin)-driven lymphocytes was shown to specifically support the proliferation of T lymphocytes and was therefore named *T-cell growth factor* (*TCGF*). Subsequently, a number of other growth and differentiation factors acting on specific cell lineages were described.

By the late 1970s, it was beginning to be realized that some of these soluble factors, which had been separately designated, were in fact either similar or identical substances. For example, the production of EP and LAF could be shown to be stimulated by the same agents and their molecular weights (mw), isoelectric points (pI), and other properties were broadly similar. Their purification initially showed that they contained similar active, but heterogenous, proteins with pIs ranging between 5 and 8. Following the coining of ''interleukin'' in 1979, LAF was redesignated as interleukin-1. TCGF became interleukin-2. This naturally started the quest for ''discovering'' more interleukins and during the 1980s, with the major advance in rDNA technology, many ''new'' interleukins were cloned. Some of these were clearly identical to specific cell growth factors, which had been partially characterized earlier; others turned out to be novel biologically active proteins. The new and ''old'' names for interleukins are summarized in Table 1. New interleukins continue to be identified right up to the present day.

Once interleukins were cloned and made available in large quantities via production in recombinant bacteria, their biochemistry and biology could be and has been thoroughly investigated. A common characteristic that has emerged from such studies is that most, if not all, interleukins have more than one biological activity and there is frequently an overlap between the spectrum of activities of one particular interleukin and another interleukin or a member of the cytokine superfamily, such as an interferon or a colony stimulating factor. This indicates a significant redundancy in the biological functions of interleukins and of cytokines in general. Such redundancy suggests that interleukins trigger convergent signaling pathways in cells, and the more recent cloning of interleukin receptors has shed some light on why this should be so. For instance, it is now known that some interleukins share nonspecific receptor components besides those components that are necessary for specific interleukin binding. Furthermore, while interleukin receptors do not contain cytoplasmic kinase domains themselves, it appears increasingly likely that they are associated with a limited number of nonreceptor kinases, which mediate the phosphorylation of nuclear transcription factors. The latter are activated by this process to bind to interleukin-responsive elements of interleukin-inducible genes and activate their transcription. The subsequent expression of interleukin-inducible gene mRNAs and protein synthesis leads to cellular responses. If two (or more) interleukins trigger the induction of a common set of genes, then the observed cellular response, for example, mitogenesis, will probably be similar. However, cells have regulatory mechanisms that control the expression of interleukin receptors and thus their responsiveness to particular interleukins. Some interleukin receptors are restricted to specific cell types or lineages,

Tab. 1 Interleukins and former nomenclature.

Interleukin	*Former names*
Interleukin-1α (IL-1α)	Endogenous pyrogen (EP); lymphocyte activating factor (LAF); hemopoietin-1 (HP-1)
Interleukin-1ß (IL-1ß)	As for IL-1α; osteoclast-activating factor (OAF)
Interleukin-1 receptor antagonist (IL-1ra)	–
Interleukin-2 (IL-2)	T-cell growth factor-1 (TCGF-1); killer helper factor (KHF)
Interleukin-3 (IL-3)	Multiple colony stimulating factor (multi-CSF); hemopoietic cell growth factor (HCGF)
Interleukin-4 (IL-4)	B-cell stimulating factor-I (BSF-I); T-cell growth factor-II (TCGF-II); macrophage activation factor (MAF)
Interleukin-5 (IL-5)	T-cell replacing factor-I (TRF-I); eosinophil differentiation factor (EDF); IgA-enhancing factor
Interleukin-6 (IL-6)	B-cell stimulating factor-2 (BSF-2); hybridoma-plastocytoma growth factor (HPGF); hepatocyte stimulating factor (HSF)
Interleukin-7 (IL-7)	Lymphopoietin-1 (LP-1); thymocyte growth factor (THGF); pre-B-cell growth factor (PBGF)
Interleukin-8 (IL-8)[a]	Macrophage-derived neutrophil chemotactic factor (MDNCF); neutrophil activating factor-1 (NAF-1)
Interleukin-9 (IL-9)	T-cell growth factor-III (TCGF-III); p40; mast-cell enhancing activity
Interleukin-10 (IL-10)	Cytokine synthesis inhibitory factor (CSIF)
Interleukin-11 (IL-11)	Adipogenesis inhibitory factor (AGIF)
Interleukin-12 (IL-12)	Natural killer stimulatory factor (NKSF); cytotoxic lymphocyte maturation factor (CLMF)
Interleukin-13 (IL-13)	P-600
Interleukin-14 (IL-14)	High molecular weight B-cell growth factor (HMW-BCGF)
Interleukin-15 (IL-15)	–
Interleukin-16 (IL-16)	Lymphocyte chemoattractant factor (LCF)
Interleukin-18 (IL-18)	Interferon gamma inducing factor
Interleukin-22 (IL-22)	IL-10-related T-cell-derived inducible factor (IL-TIF)
Interleukin-24 (IL-24)	Melanoma differentiation antigen-7 (MDA-7)
Interleukin-26 (IL-26)	AK155

[a] IL-8 is a member of the small cytokine or chemokine superfamily. There are two main subgroups distinguished on the basis of the positions of cysteine residues. IL-8 is a member of the CXC Ligand (CXCL) subgroup, which also includes platelet factor 4 (PF4), ß-thromboglobulin (ß-TG), gro-α, gro-ß, IP-10, and so on. The CC Ligand (CCL) subgroup includes monocyte chemoattractant protein-1 (MCP-1), RANTES, macrophage inflammatory proteins (MIP-1α MIP-1ß), I-309, and so on.

and their expression may also change according to the stage of cell development or differentiation.

Overall, the regulation of cellular responses by interleukins is complex, and probably even more so where they act as mixtures of interleukins or with other cytokines or other noncytokine mediators. The complex interaction of interleukins and other mediators, which is envisaged to occur *in vivo*, has often obscured the physiological roles of interleukins. However, do they have any major physiological roles or do they have one or more accessory or subordinate roles? The fact that most interleukins are inducibly, rather

than constitutively, produced and mainly affect the working of the immune system, suggests they have been evolved primarily for triggering host defense mechanisms against infectious microorganisms. They have been clearly shown to regulate both cell-mediated and humoral immunity. As such, they could also be important in antitumor mechanisms and in chronic degenerative diseases.

The role(s) of many interleukins in preventing or combating infectious or invasive diseases has been supported by numerous studies carried out in experimental animal model systems. The antitumor effect of interleukin-2 (IL-2) has looked, for example, to be the most efficacious in causing tumor regression in allogenic and xenogenic tumors in mice. These studies have stimulated clinical interest in interleukins, and in recent years many clinical trials to evaluate interleukins as anticancer agents have been carried out. IL-2 has been used extensively, but as with IFNα, its usefulness in treating cancer has appeared limited. It also causes severe side effects. Less is known generally about what clinical use other interleukins might offer; however, some such as IL-1 look to be too toxic. It is thus not at all certain that the therapeutic application of individual interleukins, which now number up to interleukin-29 (IL-29), will significantly affect the outcome or the management of clinical diseases.

2 Interleukin Proteins and Genes

2.1 Interleukin Proteins

There are now 29 distinct biologically active mediators that have been classified as interleukins (Table 1). However, the actual number of molecularly distinct proteins is larger than 29 because some interleukins are comprised of more than one molecular species, for example, IL-1, IL-8, IL-17. A comparable situation exists for the type I interferon (IFN) family, where for human IFNα in particular, there are 12 related molecular species known as subtypes. In the case of IL-1, initially three structurally related proteins, two of which are biologically active, that is IL-1α and IL-1ß, and the third, which is an inhibitor of IL-1α/ß actions, known as IL-1 receptor antagonist (IL-1ra), were identified. The latter is the only known interleukin without agonistic activity and which behaves as a competitive inhibitor of an interleukin. More recently, seven more structural homologs of IL-1 have been described, including one that is more commonly known as IL-18. Other examples of structurally related interleukins that nevertheless are designated as differently numbered interleukins, for example, IL-10, IL-19, IL-20, IL-22, IL-24, and IL-26, (IL-28, IL-29), are now known. In one or two cases, the interleukin name has proved less appropriate, for example, IL-8, which is now clearly just one of a large family of chemokines.

The interleukins exhibit a wide variety of primary structures, sizes, and post-translational modifications. At the tertiary level, however, the interleukins generally fall into but a few categories. Excluding the IL-1 and IL-8 families, the majority of interleukins are α-helical proteins, which although unrelated in amino acid sequences, fold up as 4-6-α-helix bundles. This α-helical bundle structure is common to IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-10, IL-11, IL-12, IL-13, IL-15, and most of the newly described interleukins (Fig. 1). The structures of the

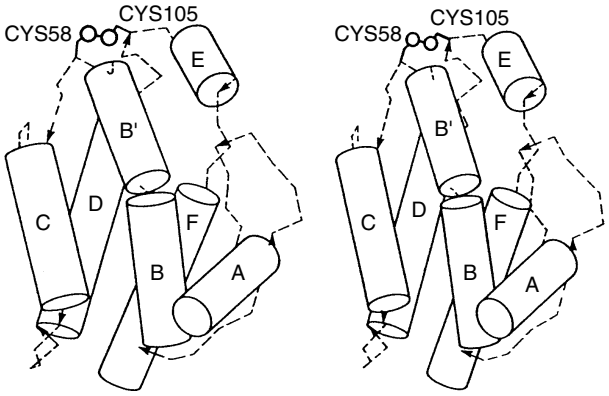

Fig. 1 Schematic stereo drawing of IL-2; helices are represented as cylinders and are lettered sequentially from the N-terminus. (Reprinted with permission from Brandhuber et al. (1987) *Science* **238**, 1707. Copyright 1987 by American Association for the Advancement of Science.)

receptors for these interleukins also have common features (discussed in Sect. 3.1). These interleukins have sometimes been referred to as *hematopoietins* and their receptors as hematopoietin receptors (HR). Interestingly, the hematopoietin family extends to other noninterleukin mediators such as erythropoietin (EPO) and growth hormone (GH) as well as a number of cytokines, including granulocyte colony stimulating factor (G-CSF), granulocyte-macrophage colony stimulating factor (GM-CSF), leukemia inhibitory factor (LIF), oncostatin M (OSM), and ciliary neurotrophic factor (CNTF). In contrast, IL-1ß and other IL-1 family members are nonhelical proteins with about 60% of residues in ß-strands, in a compact configuration known as a ß-trefoil (Fig. 2). IL-1α and ß and IL-18 are also unlike the other interleukins in having long N-terminal leader sequences (prodomains) rather than the recognizable signal polypeptides of secreted interleukins. Their processing and the exit of mature IL-1α, IL-1ß, or IL-18 from cells is therefore quite different from the other interleukins. A specific enzyme, a cysteine protease originally called IL-1ß converting enzyme but now designated caspase 1, which cleaves pro-IL-1ß to release the mature (active) IL-1ß protein, has been characterized. The IL-8 protein has a structure that incorporates both α-helical and ß-strand domains. The three-dimensional structures of the latest additions to the interleukin family are not known in detail, but are predicted to be mainly α-helical.

Another variable characteristic of interleukins is whether they are active in the monomeric or dimeric configuration. Most are active as monomers, but IL-5, IL-8, IL-10, (and IL-19, IL-20, IL-22, IL-24, IL-26) and IL-12 (and IL-23, IL-27) are dimers. Glycosylation is also a variable feature of interleukins; IL-1α and ß are not glycosylated, whereas most of the other interleukins have either O-linked and/or N-linked oligosaccharide side chains. The molecular characteristics of interleukins are summarized in Table 2.

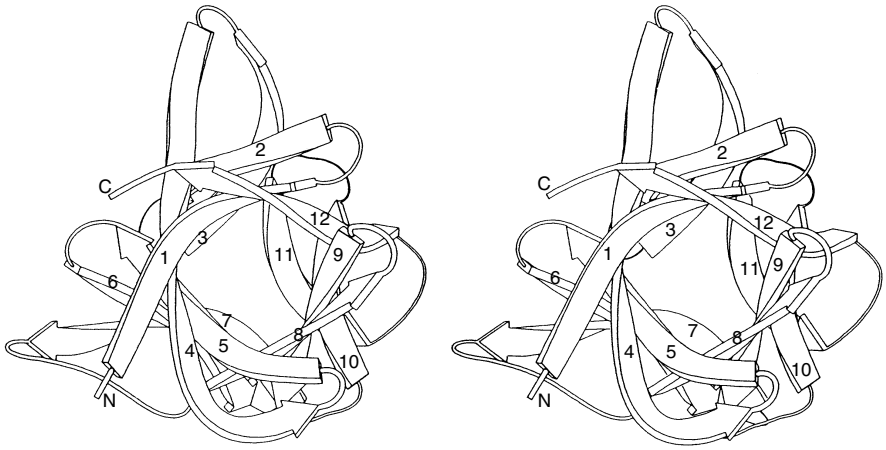

Fig. 2 Stereo cartoon of IL-1ß. The twisted arrows represent ß-strands and they are numbered sequentially from the N-terminal. The view is down the axis of the barrel formed by six of the ß-strands. 2.2 Interleukin Genes

The fact that interleukin-like molecules can be found in invertebrates indicates that interleukin genes probably arose very long ago (>500 million years). The precise ancestry of interleukin genes is not known, but it is clear that they have been conserved throughout evolution from an apparent ancient origin. The structures of interleukin genes are complex, being composed of several exons and introns (cf the intronless type I IFN genes). For example, the human IL-1ß gene, which is located on the long arm of chromosome 2, contains 7 exons and 6 introns. However, many of the other interleukin genes share a common 4-exon-3-intron structure, for example, IL-2, IL-4, IL-5, which is also found in the GM-CSF and IFNγ genes. The gene for IL-6 has 5 exons and 4 introns, a feature it shares with the G-CSF gene. The interleukin genes are widely distributed among human chromosomes (Table 2), but there are several locations where interleukin families and their receptors are clustered, for example, the genes for IL-3, IL-4, IL-5, IL-9, IL-12p40, IL-13, GM-CSF, monocyte-colony stimulating factor (M-CSF) and its receptor are linked on the long arm (q) of chromosome 5. The equivalent site in the mouse genome is located on chromosome 11.

The expression of interleukin genes is dependent upon the activation of cellular transcription factors and the binding of these to the response elements located in the 5′ flanking regions of the coding DNA. The promoters and enhancers of interleukin gene transcription have been rather less studied than, for example, those of the IFNß gene. For instance, while IL-1α, IL-1ß, and IL-1ra genes are activated by common inducers such as bacterial lipopolysaccharide (LPS) and phorbol esters, there are cellular mechanisms that give rise to differential expression of their respective mRNAs. These mechanisms are poorly understood, but are probably cell type specific. Inducers of IL-1 genes,

A growing number of additional interleukins have now been characterized; however, by and large, these belong to the previously characterized interleukin families. For instance, several IL-1 homologs have been identified, the genes of which are all on chromosome 2 close to IL-1α, IL-1β, and IL-1ra genes; in contrast, the gene for IL-18, an IL-1 paralog, is located on chromosome 11. Genes for IL-10 paralogs IL-19, IL-20, and IL-24 are located at chromosome 1q32 along with the IL-10 gene, while those for IL-22 and IL-26 are located on chromosome 12q15, close to the IFNγ gene. IL-10 and related paralogs are all V-shaped homodimers with topology resembling that of IFNγ. Receptors for IL-10 family members are constituted by specific pairs of class II cytokine receptor chains. IL-28 and IL-29 are related to both IL-10 and type I IFN families; however, their genes resemble the intron–exon structure of IL-10-type genes rather than the intronless type I IFN genes and are located on chromosome 19q13, away from either IL-10- and paralog genes, located as above, or type I IFN genes on chromosome 9. The receptor for IL-28/29 is a distinct class II cytokine receptor pair composed of IL-10Rβ and CRF2-12 and different from type I IFN receptors. IL-21 is a 4-helix cytokine most closely to IL-15; IL-23 and IL-27 are heterodimers structurally related to IL-12, IL-23 sharing with IL-12 its p40 subunit and thus one of its receptors, IL-12Rβ1.

for example, LPS, phorbol myristate acetate (PMA), increase protein kinase C (PKC) activity, which in turn activates the nuclear transcription factors, NFκB and AP-1 (composed of the protooncogene products c-jun and c-fos). Binding motifs for NFκB and AP-1 are present in the promoter regions of IL-1 genes. It is probable that transcription of IL-1 genes is regulated by activated NFκB and AP-1, although presently it is not understood how their transcription is differentially regulated. Other factors such as intracellular levels of cyclic AMP (cAMP) could be important in this respect. Increased concentrations of cAMP have been found to enhance IL-1ß expression, both at the transcriptional and posttranscriptional level. Interestingly, it is clear that IL-1α and ß can themselves induce IL-1 gene expression, probably utilizing the same PKC signaling pathway and NFκB/AP-1 transcription factors as other IL-1 inducers. However, in macrophages, LPS is by far the strongest inducer of IL-1 gene expression.

In contrast, IL-2 gene expression is dependent on mitogenic or antigenic stimulation of T lymphocytes. Gene activation requires at least three transcription factors, AP-1, and two others designated NFAT-1 and NFIL-2A, which themselves are subject to regulatory mechanisms. The signaling pathway via PKC appears to be involved in IL-2 gene induction. IL-1, which also utilizes the PKC pathway and is known to enhance IL-2 synthesis, probably acts to augment/amplify the cooperation of nuclear transcription factors at the level of the IL-2 gene. The promoter region of the IL-6 gene contains the NFκB and AP-1 binding motifs, similar to those found in IL-1 genes, plus a cAMP-responsive element (cRE).

It is known that other interleukin genes are responsive to the same or similar inducers that lead to IL-1 gene activation, for example, IL-6, IL-8, while others are responsive to the same inducers that lead to IL-2 gene activation, for example, IL-3, IL-4, IL-5, IL-7, IL-9, IL-10, and IL-13. Synthesis of the latter interleukins is almost entirely restricted to T lymphocytes, but regulation at the transcriptional level can determine which interleukins are produced. Mature T-helper (h) $CD4^+$ lymphocytes, for example, can be separated into two or more functional subsets. The Th1 subset, which is responsible for initiating responses against intracellular pathogens and delayed-type hypersensitivity, produces IL-2 and IFNγ, whereas the Th2 subset, which preferentially induces antibody-mediated responses, produces IL-4, IL-5, IL-6, IL-10, and IL-13. Other interleukins, for example, IL-3, and cytokines, for example, GM-CSF, tumor necrosis factor alpha (TNFα) may be produced by either subset (Table 3). More immature Th lymphocytes, designated Th0, appear to be able to produce an unrestricted range of interleukins and cytokines. The mechanisms by which interleukin genes are switched on and off in Th lymphocytes are not fully understood, but are partly dependent on differentiation and maturation signals mediated by other interleukins and cytokines, for example, IL-12, IFNγ, and pathogenic triggers. For example, allergens and certain parasite antigens stimulate the development of Th2 lymphocytes.

The production of interleukins is also likely to be subject to posttranscriptional and posttranslational controls. As mentioned earlier, the processing of IL-1α and ß is complex, involving specific enzyme cleavage of IL-1 31 kDa precursors and transport of the mature, active 17.5 kDa IL-1α and ß proteins through the cytoplasm to cell membrane (neither IL-1 precursors

Tab. 3 Interleukins and cytokines secreted by T-helper $CD4^+$ cell subsets and cytotoxic $CD8^+$ T lymphocytes.

nor mature forms appear to enter the endoplasmic reticulum as would a ''normal'' secreted protein). Some IL-1α appears to remain ''anchored'' in the cell membrane or the cell associated for several hours before being released, whereas IL-1ß is quickly ''secreted''. The processing of IL-1α and ß is unusual and for all of the other interleukins, including IL-1ra, processing, posttranslational modification, for example, glycosylation, and secretion occurs through the regular route for a protein containing an N-terminal signal sequence, that is, via the endoplasmic reticulum and the Golgi apparatus.

The expression of all the interleukin genes is tightly regulated. Interleukin mRNAs are usually made for only short periods of time following induction. The interleukin genes then become hyporesponsive to further stimulation, probably due to increases in the level of repressor complexes. Synthesis of interleukins is also of a relatively short duration, but can depend on the stability of the mRNA. In addition, the level of synthesis will be affected (modulated) by the presence of other active regulatory agents [(for example, immunosuppressive hormones (prostaglandins, glucocorticoids) and cytokines (transforming growth factor beta TGF-β)].

The major cell sources and inducers of particular interleukins are detailed in Table 4.

3 Interleukin Receptors

3.1 Receptor Structure

As discussed in Sect. 2.1, many interleukins have similar α-helical bundle structures and therefore it is not surprising that their cell surface receptors also share common structural features, particularly in their N-terminal extracellular binding domains. The receptors for IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-12, IL-13, IL-15, and IL-21 have been classified under the generic name of hematopoietin receptor (HR). Alternatively, they are known as type I cytokine receptors. Two

Tab. 4 Major cell sources and inducers of interleukins.

Interleukin	*Cell source*	*Inducers*
IL-1α/ß and IL-1ra	Monocytes/macrophages; endothelial cells; fibroblasts; most cell types	Bacterial lipopolysaccharide (LPS); phorbol esters; calcium ionophore; muramyldipeptide; IL-1α/ß; TNFα
IL-2	T cells	Mitogens, e.g. plant lectins and bacterial enterotoxins; antigens
IL-3	T cells; mast cells; thymic epithelial cells; keratinocytes	Mitogens and antigens (T cells) antibody cross-linking of FcR for IgE (mast cells)
IL-4	T cells; mast cells; basophils; B cells; bone marrow stromal cells	Mitogens and antigens; antibody cross-linking of FcR for IgE
IL-5	T cells; mast cells	Mitogens and antigens; antibody cross-linking of FcR for IgE
IL-6	T cells; macrophages; fibroblasts, hepatocytes; endothelial cells	LPS; phorbol esters; IL-1α/ß; TNFα/ß; calcium ionophore
IL-7	Bone marrow stromal cells; fetal liver cells	Cytokines; TGFß, PDGF and IL-1α/ß
IL-8	Wide variety of cell types, including macrophages; T cells; endothelial cells	LPS; phorbol esters; IL-1α/ß; TNFα/ß; calcium ionophore
IL-9	T cells	Mitogens and antigens
IL-10	T cells; macrophages; B cells; keratinocytes	Mitogens and antigens; LPS; EBV (transformed B cells)
IL-11	Stromal fibroblasts; trophoblasts	Cytokines; TGFß, PDGF and IL-1α/ß
IL-12	Macrophages; dendritic cells	LPS; mitogens; phorbol esters
IL-13	T cells	Mitogens and antigens
IL-14	T cells	Mitogens and antigens
IL-15	Macrophages;epithelial cells	Type I interferons
IL-16	T cells; monocytes; eosinophils	?
IL-17	T cells	Mitogens and antigens
IL-18	Macrophages	LPS
IL-19	PBMC; T- and B-cell lines	LPS; GM-CSF
IL-20	Keratinocytes; skin cells	?
IL-21	T cells	Mitogens and antigens
IL-22	T cells	LPS; IL-9
IL-23	Macrophages; dendritic cells	LPS
IL-24	Th2 cells; melanoma cell lines	IFNβ and phorbol esters
IL-25	Th2 cells; mast cells	Mitogens; antigens; IgE
IL-26	T cells	Herpesvirus transformation
IL-27	Macrophages; dendritic cells	LPS
IL-28	Dendritic cells	Virus infection; poly (I).(C)
IL-29	Dendritic cells	Virus infection; poly (I).(C)

components of the high-affinity IL-2 receptor also belong to the HR family as do the receptors for G-CSF, GM-CSF, EPO, GH, LIF, CNTF, and OSM. In addition, the two nonspecific receptor chains that are required for IL-3, IL-5, and GM-CSF receptor function and for IL-6, IL-11, LIF, CNTF, and OSM receptor function respectively, are HR family members.

The basic structural characteristics of HR are two extracellular domains of approximately 100 amino acids, the one closest to the cell membrane containing a WSXWS motif and the outer N-terminal domain containing a number of conserved cysteine residues (Fig. 3). As new members of the HR family were identified, it became clear that either (1) these two domains could be duplicated or (2) unrelated domains that were immunoglobulin-like or fibronectin-like could be added to extend the extracellular portion of the receptor. In the case of the GH receptor, which has the simplest two domain structure (Fig. 3), X-crystallography has recently shown that each of the 100 amino acid stretches consists of seven ß-strands that are folded to form a sandwich of two antiparallel sheets. However, only the N-terminal domain makes contact with the GH molecule. In fact, the GH molecule is able to bind to two GH receptors, thus effecting their dimerization, a process that is likely to be required for signal transduction via the C-terminal intracellular domains.

The G-CSF receptor probably functions in a similar manner. However, many of the interleukin receptors are more complex in that they are composed of more than one component (subunit). The IL-2 receptor, for example, has three subunits, the first (IL-2Rα) being a glycoprotein unrelated to the HR family and the second (IL-2Rß) and third (IL-2Rγ) being HR family members. All three subunits can bind IL-2 with low affinity, the complexes of α- and ß- and ß- and γ-subunits bind IL-2 with intermediate affinity, but only the complex of α-, ß-, and γ-subunits can form a high-affinity receptor for IL-2, leading to signal transduction and internalization of the ligand–receptor complex (IL-2Rγ has been shown to be a subunit of IL-4, IL-7, IL-13, IL-15, and IL-21 receptors).

In the case of IL-3, IL-5, and GM-CSF, a different receptor system has evolved whereby ligand binding to a ligand-specific receptor subunit (α-chain) induces the association of this complex with a nonspecific receptor subunit (ß-chain) that enables signal transduction to take place. Both α- and ß- chains are members of the HR family (Fig. 3). The α-chains have only small cytoplasmic domains, insufficient for signaling, and therefore the presence of the ß-chain, which does have a large cytoplasmic domain, is required for signal transduction. This receptor system explains why IL-3, IL-5, and GM-CSF share many biological activities since where cells express all three ligand-specific α-chains, signaling can only take place by interaction with the single common, nonspecific, ß-chain yielding the same cellular response.

A similar receptor system exists for IL-6 and IL-11 and the cytokines LIF, CNTF, and OSM. Here the nonspecific ß-chain has been characterized as a 130-kDa transmembrane glycoprotein (gp130) that resembles the G-CSF receptor in overall structure (Fig. 3). Only in the presence of gp130, which itself cannot bind IL-6, can a high-affinity receptor complex be formed by interaction of the IL-6 binding α-chain and signal transduction ensues. gp130 is also the ß-chain for IL-11, LIF, CNTF and OSM (gp130 can weakly bind OSM). The IL-6Rα chain may be cleaved from the cell membrane to form a soluble receptor for IL-6 (sIL-6Rα), and this can also interact with IL-6 and gp130 to trigger signal transduction. Interestingly, IL-12 has two components, a p40 subunit that is homologous to sIL-6Rα and a p35 subunit that resembles a typical helical cytokine. In effect, it is an interleukin that carries its own specific α-chain around

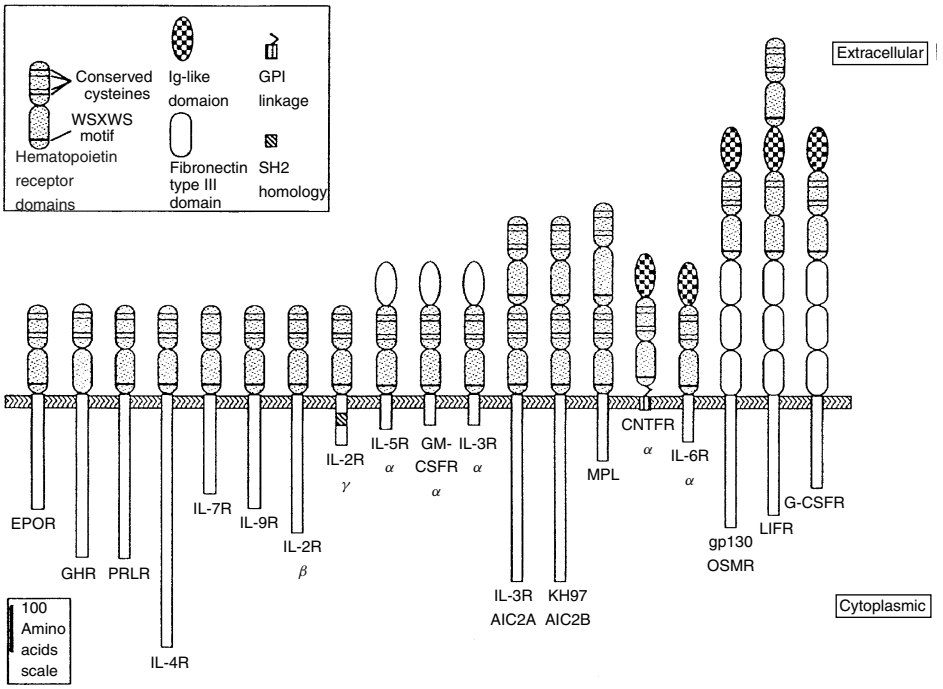

Fig. 3 Schematic receptor structures of the hematopoietin superfamily. Modular elements are as shown in the box. (Reprinted with permission of Cosman (1993) *Cytokine* **5**, 95 Copyright Academic Press Ltd.)

with it. The high-affinity receptor for IL-12 is composed of two related ß-type receptor chains, IL-12Rß1 and IL-12Rß2, each independently having low affinity for IL-12. IL-12 p40 interacts primarily with IL-12Rß1, while p35 interacts with IL-12Rß2. IL-23, which contains the p40 subunit in common with IL-12, is able to bind only to IL-12Rß1, and probably a second, as-yet unidentified, receptor subunit is required to form the high-affinity IL-23 receptor. The receptors for IL-10 and related interleukins (IL-19, IL-20, IL-22, IL-24, and IL-26) also have two subunits, a long chain with a large intracellular domain and a smaller accessory chain, which have been classified on a structural basis as type II cytokine receptors. The latter, of which 12 members (cytokine receptor family 2, CRF2-1 to CRF2-12) are now characterized, include receptors for interferons.

Unlike the two or three component receptors of most interleukins, there are two distinct single-chain receptors for IL-1 molecules. The first of these to be characterized, now known as the type I IL-1 receptor (IL-1RI), has widespread tissue distribution and is found on T cells, fibroblasts, keratinocytes, endothelial cells, synovial lining cells, chondrocytes, and hepatocytes. The second receptor, the type II IL-1 receptor (IL-1RII), is found on B cells, neutrophils, and bone marrow cells. The two receptors are about 40% related in their N-terminal extracellular domains, contain three immunoglobulin (Ig) loop structures and are therefore

included in the Ig superfamily rather than the hematopoietin superfamily. They have more recently been classified with Toll-like receptors, a family of 10 proteins involved in regulating innate immunity. The larger 80-kDa IL-1RI has an intracellular domain (217 amino acids) of sufficient size to effect signal transduction, whereas the smaller 68-kDa IL-1RII has only a short intracellular C-terminal tail and is probably not able to act as a signal transducer on its own. There is a large body of evidence demonstrating that IL-1RI is functional and is required to mediate IL-1 activities, but the biological significance of the ''incomplete'' IL-1RII is poorly understood. Recent evidence suggests IL-1RII acts as an inactive ''decoy'' receptor to bind excess IL-1ß. Expression of IL-1RI is inducible or highly regulated and this probably to some extent controls the responsiveness to IL-1α and ß, although it is known that low (5%) receptor occupancy is sufficient to trigger intracellular events. Both IL-1α and ß bind with similar affinity to IL-1RI and their binding is competitively inhibited by IL-1ra. Shortly after binding, the receptor-ligand complex is internalized and may be translocated to the nucleus.

The receptors for IL-8 and related molecules belong to a separate receptor family, that of the so-called G-protein-coupled receptor superfamily. These receptors contain seven membrane-spanning helices that couple to guanine nucleotide binding proteins (G-proteins). For IL-8, there are two distinct receptors, type I and type II (or type A and B), which are about 74% related in amino acids. It is probable that IL-8 and other members of the c-x-c subgroup of chemokines utilize these two receptors, whereas the c-c subgroup (includes MCP-1, RANTES, MIP-1α/ß) have recently been shown to bind to another G protein–coupled receptor, which has approximately 33% homology to the IL-8 receptors.

3.2 Intracellular Signaling Pathways

None of the interleukin receptors has an integral protein kinase. However, it is now known that they are associated through their intracellular domains, either directly or indirectly via adaptor proteins, with ''nonreceptor'' protein kinases to enable signal transmission to occur. For example, the intracellular domain of IL-1RI interacts with an adaptor molecule known as MyD88, which in turn couples to an ''interleukin-1 receptor associated kinase'' (IRAK). This serine kinase phoshorylates a signal transducer belonging to the tumor necrosis factor receptor associated factor (TRAF) family and this leads to the activation of nuclear transcription factors, such as AP-1 (jun/fos) and NFκB; these in turn activate IL-1 responsive genes. It is known that IL-1 can potentially induce the expression of a whole catalog of genes ranging from those of other interleukins and cytokines, for example, IL-2 to IL-8, GM-CSF, TNFα and its own family genes, that is, IL-1α/ß and IL-1ra to a wide variety of enzymes (for example, manganous superoxide dismutase, cyclooxygenase, tissue plasminogen activator, collagenase), oncogenes (*c-fos, c-jun, c-myc*), cell adhesion molecules (intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1)) and the 25-kDa IL-2 receptor chain, IL-2Rα (tac antigen). Many of these proteins are only specifically induced in certain cell types. However, mechanisms underlying such differential expression of IL-1 inducible genes remain not well understood.

It appears probable that individual interleukin receptors can be coupled to one

or more intracellular signaling pathways, usually depending on the cell type. For example, IL-1α/ß through binding to IL-1R1 can evoke PKC activity in T cells and mouse NIH 3T3 fibroblasts, whereas in human foreskin fibroblasts, the cAMP-dependent protein kinase (PKA) is activated. In Th2 cells, both PKA and PKC are evoked by IL-1. It has been reported that IL-1 triggers the formation of several second messengers, including arachidonic acid metabolites via phospholipase A_2, prostaglandins via the cyclooxygenase pathway, and ceramide via sphingomyelin. Ceramide may be responsible for activating a serine kinase, distinct from PKC, which is involved in phosphorylating the epidermal growth factor (EGF) receptor and causing a lowering of the affinity of this receptor for EGF.

As mentioned above, one of the proteins induced by IL-1 is the IL-2Rα and this, when expressed at the cell surface in combination with the two other IL-2 receptor chains, IL-2Rß and IL-2Rγ, forms the high-affinity receptor for IL-2. In contrast to IL-1RI, high-affinity IL-2R appears not to connect to signaling pathways involving phosphatidyl inositol hydrolysis, Ca^{2+} mobilization, PKC or PKA. However, IL-2 stimulation is known to result in tyrosine phosphorylation of several cytoplasmic proteins. It is now known that the intracellular domains of IL-2Rß and IL-2Rγ respectively, bind via specific tyrosine residues, the Janus tyrosine kinases JAK1 and JAK3. The JAKs constitute a family of receptor-activated kinases, which phosphorylate the members of a distinct class of transcription factors known as *signal transducers and activators of transcription* (*STATs*). Once activated, STATs translocate to the nucleus to activate transcription of IL-2 responsive genes. Increased expression of several oncogenes, including *c-myc, c-myb, c-jun, c-fos*, and src-related protein tyrosine kinase (PTK), which are probably involved in cell proliferation, are found in IL-2 activated cells. Notably, other interleukin and cytokine genes are also activated, but their expression depends on the phenotype of the lymphoid cell. For example, the Th-lymphocyte subsets Th1 and Th2 each express a defined spectrum of interleukins and cytokines (Table 3).

The high-affinity receptors for IL-4, IL-7, IL-9, IL-15, and IL-21 all share the IL-2Rγ chain, and therefore bind JAK3 and function in a similar way to the IL-2R. For example, high-affinity IL-15R also requires IL-2Rß and thus intracellular signaling pathways are likely to be identical to those triggered by IL-2. However, IL-15Rα is different from IL-2Rα and more widely expressed, suggesting a broader activity profile for IL-15. Most other high-affinity interleukin receptors are composed of two, rather than three chains – one α- and one ß-chain. In the case of IL-3 and IL-5 receptors, which share a common ß-chain, the latter is associated with JAK2, which activates STAT5. Similarly, for IL-6 and IL-11 receptors, the ß-chain associates primarily with JAK1, although other JAK family kinases might also be involved in signal transduction. In contrast, for IL-10 receptors, and those for the related interleukins IL-19, IL-20, IL-22, IL-24, IL-26, IL-28, and IL-29, both α- and ß-chains are associated with JAKs, in particular with TYK2 and JAK1 and 2; a similar association of JAK2 and TYK2 with the two receptor chains of IL-12R and IL-23R is also found. It is evident therefore that due to the sharing of JAKS and STATs, the intracellular pathways from the majority of interleukin receptors will have much in common, and that as

a consequence activities can be shared among several interleukins. However, since interleukins are in the main locally produced intercellular mediators, such activities are dependent on the cells present in the vicinity of their release expressing appropriate receptors, having functional intracellular signaling pathways and having transcriptionally activatable "interleukin-responsive" genes.

For example, IL-6 is an inducer of acute-phase proteins in hepatocytes and this has proved to be a useful system for studying the regulation of transcription of acute-phase proteins. A nuclear transcription factor, NF-IL-6, has been identified in IL-6 stimulated hepatocytes that binds to the promoter regions of acute-phase protein genes. The NF-IL-6 transcription factor is highly homologous to a liver-specific transcription factor C/EBP, a member of the so-called basic leucine-zipper family. These leucine-zipper proteins are known to bind to DNA as dimers through a leucine-zipper structure that is required for dimerization and that an adjacent basic region makes direct contact with DNA. Serine phosphorylation of NF-IL-6 is required to activate it to bind to the IL-6-response elements in acute-phase protein genes. Most of these genes share a common consensus sequence (CTGGGAA(T)), which also appears to be important in IL-6-dependent acute-phase protein gene activation. The acute-phase proteins induced by IL-6 include C-reactive protein (CRP), serum amyloid A, haptoglobulin, α1-antichymotrypsin, fibrinogen. These are largely restricted to hepatocytes, but as IL-6 is active in many different cell types, it is expected that IL-6 stimulation will lead to the enhanced transcription of a number of other genes, for example, *c-jun, c-fos*.

Members of IL-8 family bind to G-protein-coupled receptors. Binding of IL-8 to these receptors present on neutrophils triggers a large rise in intracellular Ca^{2+} and activation of PKC, suggesting that these changes are involved in signal transduction leading subsequently to neutrophil activation and the chemoattractant response. G-proteins, or heterotrimeric GTP-binding regulatory proteins, have been clearly implicated in signal transduction; pertussis toxin (*Bordetella pertussis* islet-activating protein), which blocks the activation of certain G-proteins, inhibits the IL-8 stimulated chemoattractant response. The activated G-proteins have been found to activate phosphatidylinositol phospholipase C and Ca^{2+} mobilization, subsequent PKC activation, secretion of granular enzymes, and activation of respiratory burst, and the generation of superoxide anion.

4 Biological Activities of Interleukins

There are now 29 recognized interleukins, three colony stimulating factors (G-CSF, GM-CSF, and M-CSF), and many more cytokines, for example, TNFα, LIF, OSM, CNTF, transforming growth factor ß (TGF-β), stem cell or steel factor and interferons (IFN), to cite a noninclusive list, that can affect the proliferation, differentiation, and function of cells. With the number of these biologically active mediators now in the hundreds, the number of possible combinations is astronomic. *In vivo*, it is probable that interleukins and other cytokines form the basis of a complex interactive communication network with the overall cellular responses being dependent on integrated assimilation of multiple signals. *In vitro*, it has been rarely possible to

mimic the *in vivo* situation and experimentally a highly reductionist approach using isolated molecules, isolated cells, and cell lines has formed the basis for studying the biological activities of individual interleukins. Such work has provided an important base, but is unsatisfactory in the long run as the true roles of interleukins cannot be accurately predicted. Only studies in whole animals and intact tissues will provide answers on the physiological importance of interleukins.

This section will first concisely review the biological activities of interleukins, starting with IL-1, that have been defined from *in vitro* experimentation. However, the vast amount of literature information precludes a totally comprehensive survey. Secondly, some examples of interleukin interactions will be briefly described and thirdly, the *in vivo* biological roles of interleukins, where information is available, will be outlined.

4.1 Interleukin-1

An unusually large number of biological activities have been attributed to IL-1. Broadly speaking, the activities of IL-1α and IL-1ß are qualitatively the same, and both IL-1α and ß are antagonized by IL-1ra. Currently, the activities of other members of the IL-1 superfamily, excluding IL-18, are not known. In general, IL-1α and ß behave as the primary activators of cells, readying them for secondary stimuli. As such, they have been included in a category of mediators called *competence factors*. These are considered to be elements of cell activation pathways, which commit cells to a series of stimulatable, contingent events. In this context, IL-1 has been shown to augment antigen activation of T lymphocytes and to potentiate the proliferation of hematopoietic progenitors. IL-1 has also been demonstrated to induce the synthesis of secondary acting mediators, the so-called *progression factors* that stimulate cells to undergo further proliferative or differentiating events. For example, IL-1 induces platelet-derived growth factor (PDGF), a potent mitogenic factor, in fibroblasts, GM-CSF in endothelial cells, IL-2 in T lymphocytes and IL-1, IL-6, IL-8, and TNFα in monocytes/macrophages. In addition, IL-1 can induce or regulate the expression of receptors and other cell surface molecules, for example, IL-2Rα in T lymphocytes, ICAM-1, and VCAM-1 in endothelial cells. IL-1, at least *in vitro*, can stimulate acute-phase protein synthesis in hepatocytes, although it is not as potent as IL-6 (NB possibly the effects of IL-1 on hepatocytes occur as the result of intermediate production of IL-6). At relatively high doses, IL-1 induces bone and cartilage resorption *in vitro* cell systems. In contrast, at low doses, IL-1 may promote osteoblast proliferation and transiently stimulate collagen synthesis. IL-1 induces prostaglandin (PGE_2) synthesis by synovial cells.

In hematopoiesis, that is, the generation of mature blood cells from bone marrow stem cells, IL-1 can act as activator of early progenitors, and in combination with other interleukins, for example, IL-3, IL-6, it probably stimulates proliferation and differentiation of the various cell lineages. It may synergize with IL-6 for IL-2 synthesis by activated T lymphocytes, with IL-4 for B-cell activation and Ig isotype regulation, and with IL-2 or IFN for augmenting natural killer (NK) cell activity.

In vivo, IL-1 is known to induce fever (IL-1 was originally called *endogenous pyrogen* (*EP*)), sleepiness, and anorexia. IL-1 also has been shown to affect the neuroendocrine system, principally by

increasing pituitary adrenocorticotropic hormone (ACTH) and endorphin levels as well as glucocorticoids. Administration of IL-1 causes neutrophilia, probably due to IL-1-mediated induction of GM-CSF from endothelial cells. The latter are activated and sticky for lymphocytes and monocytes due to increased ICAM-1 expression. There are effects on liver function leading to increased amino acid turnover and hyperlipidemia. By itself, but particularly in combination with TNFα and/or bacterial LPS, high levels of IL-1 can lead to profound hypotension, myocardial suppression, shock, and death.

The biological activities of IL-1 and other interleukins are summarized in Table 5.

4.2 Interleukin-2

In contrast to IL-1, IL-2 is much more limited in its biological activities, due largely to the restricted expression of high-affinity IL-2 receptors to a relatively few cell types. Mitogen- or antigen-activated mature T lymphocytes express high-affinity IL-2R and subsequent interaction with IL-2 leads to clonal proliferation. Many T-cell lines and clones, specific for particular antigens, remain wholly or partially dependent on the presence of exogenous IL-2 for proliferation. In addition, antigen-independent murine cytotoxic T-lymphocyte line (CTLL) requires IL-2 for continuous growth. NK cells, contained within the large granular lymphocyte (LGL) population, express IL-2Rß and not only proliferate in response to IL-2 but also exhibit enhanced cytolytic activity. In the presence of high IL-2 concentrations, the so-called lymphokine-activated killer (LAK) cells emerge from resting populations of lymphoid cells. LAK cells, which are cytolytic for some tumor cells, can be induced *in vitro* and *in vivo*. IL-2 can also act on activated B lymphocytes to stimulate both their proliferation and the induction of Ig synthesis.

Besides its growth-promoting activity, IL-2 stimulates T cells to secrete a range of other interleukins and cytokines (Table 3). While the principal role of these interleukins and cytokines is to act as "helper factors" for the growth and differentiation of leucocytes other than T lymphocytes, they could also be involved in the differentiation of the latter. Thus, IL-2 may indirectly regulate T-lymphocyte differentiation, for example, in the maturation of CTL or LAK to express cytolytic activity.

In vivo, IL-2 induces lymphoid hyperplasia, for example, increases in mature T cells, neutrophilia, and eosinophilia; the latter are probably indirectly caused by IL-2 induced interleukin/cytokine synthesis by activated T cells. LAK cells appear rapidly following the infusion of IL-2. However, high doses of IL-2 induce undesirable side effects such as hypotension, oliguria, fluid retention, progressive dyspnoea (difficulty in breathing), atrial arrhythmias, thrombocytopenia, and vascular leak syndrome.

4.3 Interleukin-3

IL-3 has been called the pan-specific interleukin because of its highly pleiotropic activities. Like IL-2, IL-3 acts mainly as a specific growth factor, principally affecting the proliferation and differentiation of erythroid and myeloid lineages. It has been shown to be particularly effective in stimulating the proliferation of early erythroid/myeloid progenitors, for example, in the formation of granulocyte-erythroid-macrophage-megakaryocyte colony-forming units

Tab. 5 The biological activities of interleukins.

Interleukin	*Principal activities*
IL-1α/ß	– Activates mature T cells to produce IL-2 and express IL-2R. – Costimulant of proliferation and activation of B cells and hematopoietic progenitor cells. – Induces proinflammatory cytokines, e.g. TNFα, IL-6, and other mediators depending upon cell type. – Increases expression of endothelial cell adhesion molecules. – Induces neutrophil accumulation *in vivo*. – Induces fever and hypotension.
IL-1ra	– Inhibits the activities of IL-1α/ß by competing for IL-1R.
IL-2	– Stimulates T-cell proliferation and differentiation. – Activates NK and LAK cells. – Promotes proliferation of and Ig secretion in activated B cells. – Causes vascular leak syndrome *in vivo* at high doses.
IL-3	– Acts in combination with lineage-restricted cytokines to stimulate proliferation and differentiation of hematopoietic progenitors of macrophages, neutrophils, basophils, eosinophils, mast cells, megakaryocytes, and erythrocytes. – Supports the proliferation of early multipotential bone marrow stem cells.
IL-4	– B-cell growth and differentiating factor, induces IgE synthesis. – Generates Th2 cell subset from naive Th0 cell population. – Antagonist of IFNγ.
IL-5	– Stimulates generation of eosinophils from hematopoietic precursors. – Possible involvement in B-cell differentiation and Ig class switching.
IL-6	– Growth factor for many transformed and tumor cells. – Costimulant of proliferation in thymocytes and IL-3-dependent hematopoietic progenitors, and of IL-2 production in mature T cells. – Terminal B-cell differentiation factor. – Hepatocyte stimulating factor; inducer of acute-phase protein synthesis.
IL-7	– Supports the proliferation of immature B- and T cells. – Possible involvement in proliferation and activation of mature T cells.
IL-8	– Chemoattractant for neutrophils and T cells. – Stimulates neutrophil activation and degranulation.
IL-9	– Augments mast-cell proliferation response to IL-2. – Sustains antigen-independent growth of certain Th cells.
IL-10	– Inhibitor of cytokine/interleukin synthesis by Th1 cells. – Suppressant of macrophage functions, including down regulation of inflammatory cytokine production. – Enhances B-cell proliferation and Ig synthesis. – Growth factor for B-cell tumors.
IL-11	– Synergistic factor for IL-3-dependent proliferation of bone marrow progenitors (similar to IL-6 in this respect), particularly megakaryocyte colonies. – Can act on hepatocytes to induce acute-phase protein synthesis.
IL-12	– Stimulates the differentiation of naive Th0 cells into the Th1 cell subset and thereby is an initiator of cell-mediated immunity. – Induces IFNγ production with IL-18 as costimulant. – Stimulates the proliferation and activity of NK cells and mature T cells.
IL-13	– Induces B-cell proliferation and differentiation (similar to IL-4). – Inhibits inflammatory cytokine synthesis by monocytes/macrophages.

Tab. 5 (*continued*)

Interleukin	*Principal activities*
IL-14	– Inducer of proliferation of activated B cells (but not resting B cells). – Inhibits Ig secretion by mitogen-stimulated B cells.
IL-15	– Inducer of proliferation of T cells and T-cell lines. – Activates NK and LAK cells.
IL-16	– Lymphocyte chemoattractant factor; stimulates migratory response in $CD4^+$ lymphocytes, monocytes and eosinophils.
IL-17	– Induces IL-6 and IL-8 production in fibroblasts; neutrophil recruitment. – Enhances cell surface antigen and adhesion molecule expression.
IL-18	– Induces T-cell IFNγ production in combination with IL-12. – Enhances T-cell cytotoxicity and inflammatory responses.
IL-19	– Similar to IL-10, but poorly defined as yet.
IL-20	– Involved in skin differentiation and keratin expression.
IL-21	– Regulation of NK cell activation and differentiation.
IL-22	– Activates synthesis of acute-phase proteins in liver cells.
IL-23	– Similar to IL-12, but poorly defined as yet.
IL-24	– Induction of apoptosis and inhibition of proliferation in tumor cells.
IL-25	– Induces expression of Th2 type immunosuppressive interleukins.
IL-26	– Not known.
IL-27	– Similar to IL-12, but poorly defined as yet.
IL-28/29	– Induce antiviral activity.

(GEMM-CFU) and in the stimulation of erythroid burst-forming units (BFU-E) and megakaryocyte progenitors. There is some evidence that IL-3 also acts on very early multipotential progenitor cells. IL-3 may be considered to act as a progression factor following cell activation with competence factors, such as IL-1. IL-3 may also stimulate the proliferation/differentiation of more mature cells of the myeloid lineage, for example, by inducing macrophage precursors to express cytokine receptors, such as M-CSF-R. There is experimental data showing that IL-3 has a growth-supporting activity for murine mast cells, but it is not clear that this is so for human mast cells.

In vivo, release of IL-3 by injected WEHI-3B tumor cells results in the stimulation of all of the various types of hematopoietic cells predicted from the *in vitro* investigations, that is, increases in numbers of myeloid cells, erythroid cells, mast cells, and megakaryocytes. Administration of IL-3 to mice, primates, and humans yields broadly similar effects; the progenitors of mast cells, neutrophils, and macrophages are increased.

4.4 Interleukin-4

IL-4 was originally discovered by its action on B lymphocytes and was the first B-cell stimulating factor (BSF-1, Table 1) to be characterized. B lymphocytes, which express surface Ig, were found only to proliferate in response to anti-Ig if IL-4 (BSF-1) was present. It would appear that IL-4 is a B-lymphocyte competence factor, perhaps the counterpart of IL-1 for T lymphocytes. As such, IL-4 is involved in B-lymphocyte activation, rather than proliferation, resulting in, for example, the increased expression of

cell surface molecules, such as major histocompatibility complex (MHC) class II antigens, low-affinity IgE receptor (CD23) and surface IgM. IL-4 also regulates which Ig isotype is synthesized and secreted by mature B cells; it appears to be directly responsible for switching on IgG1 and IgE synthesis *in vitro*. This action is opposed by IFNγ, which preferentially induces the synthesis of IgG2a.

Additionally, IL-4 can act on other cell lineages. In particular, it drives the differentiation of naive T lymphocytes into the Th2-lymphocyte subset, possibly by blocking the synthesis of its own natural antagonist, IFNγ. In some antigen-independent T-cell lines, IL-4 can act as a proliferation signal, similar to IL-2. In contrast, IL-4 has been reported to antagonize the stimulatory actions of IL-2, for example, in LAK cells. IL-4 has also been shown to affect hematopoiesis, especially the development of mast cells and eosinophils from progenitor cells. It has a variety of actions in monocytes/macrophages, for example, upregulation of low-affinity IgE receptor (CD23), enhancement of MHC class II antigens, inhibition of spontaneous and induced IL-1, IL-6, IL-8, and TNFα synthesis, but stimulation of G-CSF and M-CSF, and in granulocytes, fibroblasts, epithelial, and endothelial cells. IL-4 has many activities in common with IL-13 with which it shares receptor components (see Sect. 4.13).

In vivo, IL-4 release results in the generation of large numbers of eosinophils (through induction of IL-5 production), mast cells, and macrophages. In transgenic mice, expressing IL-4 in the thymus and T cells, thymic hypoplasia, eosinophilia, and eye inflammation (possibly due to activated macrophages) have been found.

4.5 Interleukin-5

It is known that the control of eosinophil numbers is T cell dependent. In steady state hematopoiesis, relatively few eosinophils are found in the circulation. In the presence of IL-3 and GM-CSF, only small numbers of eosinophil colonies develop from GEMM-CFU progenitor cells. However, infection by parasites, such as helminths, dramatically increases eosinophil numbers and the factor responsible for eosinophil proliferation and differentiation has been identified as T-cell-derived IL-5. The main action of IL-5 is to stimulate the proliferation and maturation of eosinophil precursors (Eo-CFU); IL-5 appears to be lineage specific and does not induce the proliferation of other myeloid lineage precursors. This could be linked to the restricted IL-5Rα chain expression to eosinophils. IL-5 activity in eosinophils is probably enhanced by the actions of other interleukins, such as IL-3 and IL-4.

In addition to its growth-promoting and differentiating effects in immature eosinophils, IL-5 also acts on mature eosinophils, for example, increasing phagocytosis, killing of antibody-coated tumor cells, stimulation of superoxide (O_2^-) production. IL-5 has been demonstrated to induce the differentiation of murine- but not human-activated B lymphocytes. This activity is only apparent if the B lymphocytes have been activated by a priming stimulant such as LPS, anti-immunoglobulin, or specific antigen. IL-5 alone preferentially enhances IgA production, while specific combinations of IL-5, IL-2, and IL-4 appear to regulate the amount of IgG1 isotype synthesis.

In vivo, IL-5 causes eosinophilia, an expected result from its *in vitro* activities. In

transgenic mice that constitutively express IL-5 in their T cells, massive eosinophilia with eosinophil infiltration of tissues was observed, although in all other respects such mice remained normal and healthy.

4.6 Interleukin-6

The biological activities that are associated with IL-6 are very wide ranging – it has been shown to be very pleiotropic, indicating that IL-6R are expressed on many cell types. Originally, it was described as a B-cell stimulating factor (BSF-2, Table 1) and it is clear that IL-6 is a growth and differentiation factor for a variety of B-lymphoid cells. It is a growth factor for many murine antibody-secreting hybridomas, for some human myelomas, and for low-density cultures of human B cells transformed with Epstein–Barr virus (EBV). IL-6 is also a late-acting differentiating factor in mature B lymphocytes; their terminal differentiation into Ig-secreting plasma cells appears to be upregulated by IL-6. For T cells, IL-6 probably acts as a costimulant (secondary signal) for proliferation of thymocytes and IL-2 production by mature T cells. In hematopoiesis, IL-6 acts as a costimulant for IL-3-dependent proliferation of multipotential cells and induces maturation of megakaryocytes leading to increased platelet number. It may also stimulate the proliferation of myeloid leukemic blast cells and keratinocytes.

A major activity of IL-6 is that of a ''hepatocyte stimulating factor'', principally as an inducer of acute-phase proteins. IL-6 induces a variety of acute-phase proteins, including fibrinogen, α-1-antichymotrypsin, α1 acid glycoprotein and haptoglobulin, from the hepatoma cell line, Hep2G, and primary hepatocytes (which also produce C-reactive protein (CRP), serum amyloid A and α-1-antitrypsin)). *In vivo*, levels of IL-6 are positively correlated with levels of CRP. Serum levels of IL-6 also correlate well with fever. In transgenic mice that constitutively express IL-6 in their B cells, IgG1 plasmacytosis is developed with the infiltration of plasma cells into lung, spleen, and kidney. In contrast, infection of bone marrow cells with an IL-6 expressing recombinant retrovirus resulted in a fatal myeloproliferative disease with massive neutrophil infiltration of lungs, liver, and lymph nodes, but no plasmacytosis.

4.7 Interleukin-7

IL-7, which is produced by bone marrow stromal cells, appears to be principally involved in stimulating the growth and differentiation of cells of the lymphoid lineages. In particular, it has been shown to induce the proliferation of precursors of B lymphocytes, the so-called pro-B-cells, *in vitro*. In addition, IL-7 can stimulate the proliferation of thymocytes; it has been demonstrated to act synergistically with IL-1 in this respect. Probably, IL-7 occupies a pivotal role in T-cell development, but it also may be involved in differentiation of mature T lymphocytes. Here IL-7 may act rather like IL-6 as a costimulant of IL-2 production by T lymphocytes. Possibly IL-7 can also substitute IL-2 as a mitogen in the generation of CTL and LAK cells.

In vivo, it is likely that IL-7 activities mirror those found *in vitro*. For instance, in transgenic mice expressing IL-7 in lymphoid organs, increased numbers of both B and T cells were observed. In some transgenic mice, the continuous secretion of IL-7 has led to lymphoproliferative disorders, including B and T lymphomas.

4.8
Interleukin-8

IL-8 is the name given to just one of a number of related chemokines that are induced by inflammatory stimuli, for example, LPS, IL-1, and that act as chemoattractants for particular cell types, neutrophils, in the case of IL-8. Thus, release of IL-8 from infiltrating or tissue macrophages specifically recruits neutrophils to sites of injury or infection. IL-8 also acts on neutrophils to induce respiratory burst responses and degranulation, resulting in the superoxide ion (O_2^-) production and the release of lysosomal enzymes. In addition, IL-8 has been demonstrated to be a chemotactic and activating agent for about 10% of T cells and some basophils *in vitro*. However, it is not chemotactic for blood monocytes, the role for this being assigned to another member of the IL-8 superfamily, namely, the monocyte chemoattractant protein-1 (MCP-1). (NB IL-8 is a member of the c-x-c intercrine α-subgroup, while MCP-1 is a member of the c-c intercrine ß-subgroup).

IL-8 has been recovered from inflammatory sites such as psoriatic lesions, the synovial fluid of rheumatoid arthritis patients, and the bronchial lavage fluid taken from patients with acute respiratory distress syndrome. Injection of IL-8 leads to local neutrophil infiltration in both rabbits and humans. If repeatedly injected, IL-8 appears to cause neutrophil accumulations in joints and lungs, and may be associated with damage to cartilage and pulmonary inflammation.

4.9
Interleukin-9

IL-9 is produced by Th1 cells and has been shown to sustain the antigen-independent growth of certain Th-cell clones and lines *in vitro*. Subsequently, mouse IL-9 has also been shown to enhance the growth of bone marrow–derived mast-cell lines in response to IL-3, and that of fetal thymocytes in response to IL-2. In addition, human and mouse IL-9 act to enhance erythroid burst-forming (BFU-E) activity and human IL-9 acts to stimulate proliferation of the human megakaryoblastic leukemic cell line, MO7E. Human IL-9 can synergize with stem cell factor (SCF) and/or EPO in the stimulation of growth of this megakaryoblastic cell line and megakaryocytic progenitors.

An IL-9-dependent cell line that was transfected with the IL-9 gene to give deregulated IL-9 expression became highly tumorigenic in mice. This suggests that uncontrolled expression of IL-9 can support T-cell proliferation *in vivo*, and may be a transforming event involved in the development of certain T-cell lymphomas.

4.10
Interleukin-10

IL-10 is produced by activated Th2 lymphocytes, macrophages, and B lymphocytes and was originally characterized as a cytokine synthesis inhibitory factor (CSIF) because it inhibited IFN-γ synthesis in T cells. It also appears that IL-10 actively suppresses the development of the Th1 subset of Th lymphocytes. This probably occurs as a result of the immunosuppressive activity of IL-10 on macrophages leading to the inhibition of IL-12 production. IL-12, produced by activated macrophages and dendritic cells, stimulates Th1 lymphocyte proliferation. IL-10, in possible synergy with IL-4 and transforming growth factor ß, also blocks the production of IL-1 and TNFα by macrophages and the development of macrophage cytotoxicity and thus

can be considered as an anti-inflammatory agent. In contrast, IL-10 enhances B-cell proliferation and Ig synthesis.

Th1 cells are generally host-protective for several infectious diseases. Therefore, the suppression of Th1 cell activities will favor the growth of the infecting agent. In this context, it is interesting that EBV and several other large DNA viruses encode (viral) IL-10 molecules with limited homology to IL-10, but which act through IL-10R and thus have the same activities as IL-10. These viral IL-10 homologs appear to induce immunosuppression, thus providing an immune-evasion mechanism for such viruses. In contrast, the paralogous IL-10-related proteins, IL-19, -20, -22, -24 -26, -28, and -29 with similar limited homology to IL-10, act through distinct heterodimeric receptors composed of receptor chains belonging to the type II cytokine receptor family, which also includes receptors for interferons.

4.11
Interleukin-11

IL-11, produced by bone marrow–derived stromal cells, appears to be intimately involved in hematopoiesis and, in particular, the generation of megakaryocytes. *In vitro* studies suggest that IL-11 is capable of directly supporting the proliferation of committed murine myeloid progenitors and, like IL-6 and G-CSF, acts synergistically with IL-3 to shorten the Go phase of the cell cycle in early progenitors. Although IL-11 has no inherent megakaryocytic colony stimulating activity, it can synergize with IL-3 in stimulating human and murine megakaryocyte colony formation.

In many respects, the activities of IL-11 are very similar to those of IL-6. For example, like IL-6, IL-11 has been found to promote an increase in the number of Ig-secreting B cells. It has also been shown to stimulate the proliferation of an IL-6-dependent murine plasmacytoma cell line, and to act as an autocrine growth factor for human megakaryoblastic cell lines. Lastly, IL-11 appears to stimulate the synthesis of hepatic acute-phase proteins, but is less effective than IL-6.

4.12
Interleukin-12

The actions of IL-12 are primarily on T cells and NK cells. It appears to be a necessary factor in the generation of Th1 lymphocytes from naive or uncommitted T cells. In addition, there are results that indicate that IL-12 stimulates IFNγ production by T cells and NK cells by cooperation with either IL-1, or IL-18, or TNFα. The presence of IFNγ may also favor the development of the Th1 subset by inhibiting the production of IL-10 by macrophages. IL-12 appears to be an important factor for the differentiation and maturation of dendritic cells.

The emerging experimental data for IL-12 therefore strongly suggest that it plays an important part in the initiation of immune responses by providing a link between natural resistance mediated by phagocytic cells, for example, macrophages, and NK cells and adaptive immunity mediated by Th cells, CTL, and B cells. In support of this proposed role, recombinant IL-12 has recently been shown to cure mice infected with the parasite, Leishmania major. A neutralizing antibody against IFNγ abrogated the curative effect of IL-12 indicating that IL-12 was acting by stimulating T-cell and/or NK-cell IFNγ-production *in vivo*, and the development of a protective Th1-cell immune response. Conversely, generation of Th2 cells and associated immune responses was inhibited.

4.13
Interleukin-13

IL-13 bears approximately 30% homology with IL-4 and appears to act very similarly to IL-4. In particular, IL-13, like IL-4, induces IgE and IgG4 synthesis by human B cells. In addition, IL-13 inhibits inflammatory cytokine production by macrophages and monocytes, another activity characteristic of IL-4. Recent studies indicate that IL-13 and IL-4 share receptor components, that is, the IL-4Rα and IL-13Rα1 chains, which together form high-affinity receptors for either IL-4 or -13, thus offering an explanation of their similar activities. Emerging experimental evidence suggests a more complex picture with receptors for IL-13 being constituted from among four components, including IL-13Rα1, IL-13Rα2, IL-4Rα, and IL-2Rγ.

4.14
Interleukin-14

IL-14 is a high molecular weight B-cell growth factor. However, it appears to act as a costimulant, that is, it induces the proliferation of activated B cells, but not resting B cells. It has been speculated that human IL-14 fulfills a similar role to murine IL-5 for B cells. IL-14 has also been demonstrated to inhibit Ig synthesis by mitogen-activated B cells.

4.15
Interleukin-15

IL-15 is a 14 to 15-kDa glycoprotein with shared bioactivities, but no sequence homology, with IL-2. Its biological activities are remarkably like those of IL-2 and include the induction of proliferation of the established T-cell line CTLL.2 and mitogen-stimulated peripheral blood mononuclear cells (PBMC) as well as the generation of cytolytic NK and LAK cells. The overlap of IL-15 activities with those of IL-2 is probably largely accounted for by their sharing both the IL-2Rß and IL-2Rγ chains as components of their respective high-affinity receptors.

4.16
Interleukin-16

IL-16 (or lymphocyte chemoattractant factor) is an atypical interleukin, possibly produced as a degradation product of a larger protein of 42 kDa present in lymphocytes, which probably utilizes CD4 receptors. Nevertheless, IL-16 has been shown to stimulate a migratory response in $CD4^+$ lymphocytes, monocytes, and neutrophils, upregulate IL-2 receptors and class II MHC antigens in resting T lymphocytes and exhibit some anti-HIV activity.

4.17
Interleukin-17

IL-17 is the prototypic member of a family of structurally related IL-17 proteins (6 human members A–E) produced by T lymphocytes. IL-17 appears to act like IL-1 by inducing IL-6, IL-8, and G-CSF synthesis and enhancing expression of the cellular adhesion molecule ICAM-1 in human fibroblasts. Thus, IL-17 is representative of those cytokines involved in initiating inflammatory responses and innate host defense mechanisms, for example, the pulmonary recruitment of neutrophils and microbial host defense in response to the lung pathogen *Klebsiella pneumoniae*. It may also promote the development of hematopoietic precursors.

4.18
Interleukin-18

IL-18, formerly known as *interferon gamma inducing factor* (*IGIF*) and now known to be structurally related to IL-1, appears to be mainly involved in the augmentation of Th1 cellular immune responses to invading pathogens. Its capacity to induce IFNγ is reliant on the costimulation of T lymphocytes by IL-12, whose synthesis is induced by bacterial LPS in monocytes/macrophages. It has also been shown to enhance Fas ligand-mediated cytotoxicity of cloned murine Th1 cells, but not Th0 or Th2 cells. Its activities are mediated by IL-1 receptor-related protein (IL-1Rrp), an Ig superfamily member related to IL-1RI, and can be inhibited by a naturally occurring, specific IL-18 binding protein.

4.19
Interleukin-19

IL-19, one of several IL-10 paralogs, is produced mainly by LPS-stimulated monocytes and macrophages and in common with IL-10 is expected to exert immunoregulatory functions that influence the activities of many of the cell types in the immune system. It appears probable that IL-19 will, like IL-10, act as a feedback inhibitor of proinflammatory cytokine, for example, IL-1, TNFα synthesis and thus initiate immunosuppressive effects.

4.20
Interleukin-20

IL-20, one of several IL-10 paralogs, is in contrast to IL-10 and IL-19 produced mainly by skin cells, and is thus expected to target distinctive activities on typical skin cells such as keratinocytes, which express its specific heterodimeric receptor, IL-20R1/IL-20R2. Overexpression of IL-20 has been shown to result in severe skin abnormalities, including hyperkeratosis, hyperproliferation, and aberrant epidermal differentiation.

4.21
Interleukin-21

IL-21, which is most closely related to IL-15, is one of the several structurally related cytokines, including IL-2, which is secreted by activated $CD4^+$ T cells as part of the normal response to foreign antigens. Its main role appears to be as a differentiation factor for NK cells. It has been shown to promote IFNγ synthesis, which acts to enhance macrophage killing of microbial pathogens, and to prevent apoptosis of precursor NK cells, allowing them to become terminally differentiated and fully activated.

4.22
Interleukin-22

IL-22, one of several IL-10 paralogs, formerly known as IL-10-related T-cell-derived inducible factor (IL-TIF) is primarily produced by activated $CD4^+$ T cells, but unlike immunoregulatory IL-10, its target cell types include mesangial, neuronal, and liver cells (hepatocyctes). Its action on hepatocytes (and hepatoma cell lines) appears similar to that of IL-6 in that it results in the upregulation of a number of acute-phase proteins. It should therefore probably be included with other proinflammatory cytokines as a prime mediator of the acute-phase response.

4.23
Interleukin-23

IL-23, produced mainly by macrophages and dendritic cells, is a novel heterodimeric cytokine constituted by the p40 subunit of IL-12 and a p19 subunit that is most closely related to the p35 subunit of IL-12. It is evident that IL-23, besides sharing one structural subunit with IL-12, also shares IL-12Rβ1 of the high-affinity IL-12R as part of IL-23R. However, a second specific IL-23R component is indicated for the recognition of p19 suggesting IL-23 has distinct cell targets from IL-12. For instance, although IL-23 in common with IL-12 stimulates IFNγ production, IL-23 is a strong inducer of memory T-cell proliferation, while IL-12 is not. In addition, IL-23, in contrast to IL-1, for example, appears to act more broadly as an end-stage effector cytokine via direct actions on macrophages.

4.24
Interleukin-24

IL-24, one of several IL-10 paralogs, formerly known as melanoma differentiation-associated antigen 7 (MDA7), was originally found to be expressed in differentiated melanoma cells, but is now also known to be expressed by a variety of cell types, including T lymphoblasts. IL-24 appears to act through IL-20R and thus is expected to have similar cell targets to IL-20. It has been demonstrated to have antiproliferative activity against cultured tumor cell lines, including those derived from melanomas.

4.25
Interleukin-25

IL-25, also known as SF20, is a novel cytokine belonging to the IL-17 family, which is mainly produced by Th2 cells. It has been shown to induce expression of the immunosuppressive interleukins, IL-4, IL-5 and IL-13, required for Th2-like responses and may thus be an important mediator of allergic disease.

4.26
Interleukin-26

IL-26, one of several IL-10 paralogs, also previously known as AK155, is expressed at high levels in activated T cells, monocytes, and various T-derived leukemic cell lines. However, little is yet known about its cell targets and biological activities.

4.27
Interleukin-27

IL-27 is a newly identified ''IL-12-like'' heterodimeric cytokine, also similar to IL-23. It is constituted by Epstein–Barr virus-induced gene 3 (EBI3) protein, a protein that is widely expressed and related to IL-12 p40 subunit and a further homolog of IL-12 p35 known as p28. IL-27 is the product of activated antigen-presenting cells (macrophages and dendritic cells) and stimulates the rapid clonal expansion of naïve but not memory $CD4^+$ T cells. It also strongly synergizes with IL-12 to trigger IFNγ production by naïve $CD4^+$ T cells.

4.28
Interleukin-28

IL-28 consists of two near identical proteins, IL-28A and B, which are distantly related to both the IL-10 and IFNα families, which are induced by viral infection. They interact with a heterodimeric class II cytokine receptor that consists of IL-10Rβ chain and an orphan class II receptor

chain designated IL-28Rα. IL-28 induces interferon-stimulated response elements (ISRE), but not via IFN receptors, and mediates moderate antiviral activity in response to virus infection. This has led to IL-28A and B being also named as IFNs, IFN-lambda2, and -lambda3, respectively. In common with IFNs, IL-28 upregulates several known IFN-responsive genes, including MxA, 2-5A synthetase, and class I MHC antigen.

4.29 Interleukin-29

IL-29 shows 81% sequence homology to IL-28 and acts in a very similar way. It also has been shown to induce IFN-responsive genes and exert antiviral activity, and thus is alternatively designated IFN-lambda1.

5 Interleukin Physiology

Interleukins are mainly, but not exclusively, inducible mediators of nonspecific host resistance and adaptive immunity, that is, they are stimulators of host-protective mechanisms against infectious and invasive diseases. The biological effects of most interleukins are readily observable *in vivo*. However, the administration of high doses of a single interleukin by abnormal routes may also create imbalances that perturb homeostatic mechanisms resulting in aberrant biological and physiological responses. Therefore, studies in which deficiencies of interleukin production or action can be investigated can provide perhaps a better guide to the physiological role(s) of individual interleukins. Such studies can either be done by blocking interleukin action, for example, with anti-interleukin antibodies, antireceptor antibodies, or soluble receptors, or by examining the effects of genetic deficiencies in interleukin protein or receptor. The former are probably the less satisfactory of the two approaches since interleukin production needs to be stimulated before an effect of an inhibitor of interleukin action can be demonstrated. Generally speaking, it is not possible to induce the production of a single interleukin; several interleukins and cytokines are normally produced in response to a stimulant. In addition, most antibodies used will be foreign (xenogenic) to the responding animal, and this may result in problems of an immunological nature.

There have been very few natural genetic deficiencies in interleukin genes and interleukin-receptor genes identified so far. However, it is now possible to artificially create knockout mutations in mice by using the strategy of gene targeting in embryonic stem (ES) cells. Increasing numbers of different knockout mice are being created, and it is perhaps surprising that some of them apparently develop normally, are born alive, and can grow and survive for weeks, if not months. Possibly, compensatory molecules or mechanisms are induced in these knockout mice. In the IL-2 knockout or null mouse, for example, development is normal with no effects being observed on the early development of thymocytes and inactivation of T lymphocytes within the thymus. However, a lack of response of mature T cells to polyclonal activators together with a lack of T cell–mediated ''help'', that is, interleukin production, for B-cell growth and differentiation were manifest in these mice. There were also excessively high levels of IgG1 and IgE found. About half of these mice became severely immunocompromised and died between four and nine weeks from

birth. The remainder developed an inflammatory bowel disease, probably resulting from an abnormal immune response to a normal antigenic stimulus. In man, a child with a defect in IL-2 mRNA production (but not due to a defect in the IL-2 gene) was found to be more susceptible to infections. In addition, a few patients suffering from a particular form of severe combined immunodeficiency disease (SCID), which has been linked to the X chromosome (thus XSCID), are characterized by a lack of expression of IL-2Rγ. XSCID patients are therefore unable to form high-affinity IL-2 (or IL-4, -7, -9, -15, -21) receptors and their immunocytes cannot respond to IL-2 or the other interleukins that require IL-2Rγ. In total, these studies provide strong evidence for IL-2 playing a key role in the regulation of immune and inflammatory responses. In contrast, either IL-15 or IL-15Rα knockout mice are lymphopenic with selective loss particularly of NK and $CD8^+$ T-cell subsets, rendering these mice susceptible to vaccinia virus infection. Thus, this phenotype is distinctive from that of IL-2 knockouts and indicates a role different to IL-2 for IL-15, despite the latter sharing two of the high-affinity IL-2R components (see Sect. 4.15).

Other knockout mice that are interesting in this respect are those of the IL-4 and IL-10 null phenotypes. In IL-4 knockout mice, it has been found that they generally are unable to mount a Th2 cell type of immune response. For instance, IgE was undetectable in these mice. In addition, when these mice were parasitized with the nematode *Nippostrongylus brasiliensis*, only a weak eosinophilia was observed. Since eosinophil proliferation is dependent on IL-5 (see Sect. 4.5), this finding indicates that IL-4 is required for inducing Th2 cell interleukin production, that is, IL-4, IL-5, IL-10, and so on. In the case of IL-10 knockout mice, it might be expected that these animals are also less able to mount a Th2 cell immune response, since loss of IL-10, which actively suppresses macrophage ''help'' (IL-12) for Th1 cell generation, would relieve the inhibition on Th1 cell development. However, the main observable effect in IL-10 knockout mice is chronic bowel inflammation where mice are not kept under specific pathogen-free conditions. This finding indicates that IL-10 acts as a regulator of immune responses stimulated by enteric antigens in the intestine. In the absence of IL-10, such immune responses are uncontrolled leading to bowel inflammation, probably due to a loss of IL-10-mediated suppression of macrophage cytotoxicity and release of inflammatory cytokines, for example, IL-1, TNFα. In support of this hypothesis, it has been shown that normal mice become more sensitive to LPS-induced endotoxic shock by treatment with anti-IL-10 antibodies, while lethal endotoxemia and elevated serum TNFα levels were suppressed by injected IL-10.

Another interesting cohort of interleukin knockouts that is currently emerging is that with knockouts of IL-12 or IL-23. Knockouts of IL-12 p40 (which lack both IL-12 and IL-23) are more immunocompromised than knockouts of IL-12 p35 (which lack only IL-12). However, knockouts of IL-23 p19 (which lack only IL-23) manifest a phenotype that can be distinguished from the p35 knockout. The p19 null mice can still generate Th1 cells and IFNγ, but are susceptible to experimental autoimmune encephalitis (EAE), whereas p35 null mice cannot generate Th1 cells, but are highly susceptible to EAE. Such studies indicate the importance of the interleukin recognition components of their cognate receptors in determining their functional roles.

An alternative method for determining *in vivo* roles of interleukins involves neutralizing their biological activity with specific antibodies, soluble receptors, and other antagonists, that is, essentially preventing the interaction of the interleukin with its cognate receptors, also generates interesting results. To date, however, the abrogation of interleukin activities has mostly been carried out under conditions in which pathological conditions have been induced, for example, microbial challenge, tissue injury, graft-versus-host disease, or autoimmune disease. From these studies, for example, for IL-1, it has been shown that neutralizing antibodies suppress cell-mediated immunity and increase susceptibility to pathogens such as *Listeria monocytogenes*. In this case, the IL-1ra and soluble IL-1R can also produce similar effects. Such work indicates a protective role for IL-1. Interestingly, supportive evidence for this has been revealed by a series of recent findings that members of certain virus families, particularly the poxvirus family, encode soluble homologs of interleukins or their receptors, suggesting that some viruses have evolved means of countering host-defense mechanisms that would otherwise inhibit their replication. For example, vaccinia and cowpox viruses encode a soluble form of IL-1RII that can compete for IL-1 binding to cell surface receptors and thus reduce IL-1 actions. Besides this, the IL-1RII homolog, cowpox virus has also been found to encode for an inhibitor, a serpin, of the IL-1ß converting enzyme, and this too would be expected to inhibit an IL-1ß-driven immune response from being mounted. The example of the Epstein–Barr virus encoded homolog of IL-10 has been previously discussed under Sect. 4.10.

6 Pathophysiology and Disease Correlates

There are a large number of examples of interleukins having pathophysiological roles or disease correlates, regrettably far too many to be covered here, which may help understand the complex and versatile nature of interleukins in health and disease. Starting with IL-1, it is clear that when produced at low levels it has a protective role, but when produced at high levels, which spill into the circulation, it produces a predominance of proinflammatory effects that are correlated with disease states such as hypotensive shock and sepsis. High levels of IL-1 can induce bone and cartilage resorption and degradation and IL-1ß has been found in the synovial fluid and serum of rheumatoid arthritis (RA) patients. Other inflammatory cytokines such as TNFα can also be found in RA synovial fluids. Serum or plasma IL-6 levels can be greatly increased by bacterial infections and result in acute-phase responses. IL-8 levels are raised in psoriasis scales. IL-10 levels can be raised in malignant B-cell lymphomas in AIDS patients.

Studies in transgenic mice where expression of interleukin genes is under the control of constitutive promoters have also contributed evidence of pathophysiological effects. For example, IL-2 expression in many body organs of transgenic mice leads to baldness and interstitial pneumonia due to an inflammatory infiltrate. In contrast, IL-2 expression in the pancreas leads to a lethal pancreatitis, but not diabetes. Constitutive expression of IL-5, IL-6, and IL-7 can result in the expected hyperplasias, that is, eosinophilia (IL-5), plasmacytosis (IL-6), lymphocytosis (IL-7). However, the site and control of IL-6 expression, for example, is important in determining the

outcome. When IL-6 is expressed under the control of the human Ig heavy chain promoter in B cells, the result is IgG1 plasmacytosis and infiltration of plasma cells into lung, spleen, and kidney. If, however, IL-6 is expressed under the control of the human keratin (K14) promoter in skin and tongue, there is growth retardation, poor hair growth, and epidermal scaliness (tail, paws), but no changes typical of psoriasis. By contrast, if bone marrow cells are infected with an IL-6-expressing recombinant retrovirus, a fatal myeloproliferative disease with massive neutrophil infiltration of lungs, liver, and lymph nodes develops within four weeks of engraftment, but no plasmacytosis occurs. As a further example of the diverse outcomes of constitutive interleukin expression, it has been found that IL-4 expression in the thymus and T cells results in thymic hypoplasia, inflammatory ocular lesions (blepharitis), and raised IgE and IgG1 levels, whereas IL-4 expression in B cells results in raised IgE and IgG1, but no thymic hypoplasia or blepharitis. Such differences indicate an importance of where or in which cells an interleukin is expressed, together with the quantitative and temporal elements, on the outcome.

7 Clinical Uses of Interleukins

The biological activities of interleukins have suggested that some may be of clinical use as therapeutic agents in human diseases as shown in Table 6. For example, the stimulating activity of IL-2 on the cytotoxic function of NK and LAK cells against tumor cells *in vitro* suggested that IL-2 had potential as an anticancer agent. Thus, once adequate amounts of recombinant IL-2 (rIL-2) became available, clinical trials to evaluate rIL-2 in different human malignancies were carried out. It was quickly established that high-dose IL-2 therapy caused severe side effects, for example, hypotension, oliguria, fluid retention, breathing difficulties, heart problems, with the dose-limiting side effect being the so-called *vascular leak syndrome*. In the latter, fluid extravasation and subsequent edema (swelling) takes place in the pleural and peritoneal cavities. The underlying cause appears to be the adherence of IL-2-activated lymphocytes to vascular endothelial sites, that is, the linings of blood vessels, resulting in holes in the endothelial cell layer being produced through which fluids leak. Despite these severe side effects, some tumor responses were found in a limited number of malignancies, including renal cell carcinoma, melanoma, and non-Hodgkins lymphoma. However, overall response rates with IL-2 as a single agent have been disappointingly low. New strategies involving combinations of IL-2 with other cytokines (e.g. IFNα, TNFα), antitumor monoclonal antibodies, cytotoxic drugs, or LAK cells removed by leukopheresis, activated by IL-2 and grown *ex vivo* before reinfusing back into the patient, have or are being tested in order to improve efficacy. The most ''successful'' approach has been that of adoptive cellular therapy where activated LAK cells are combined with high doses of IL-2. However, this is a highly aggressive antitumor therapy, which has serious complications for patients, with major life-threatening side effects. Despite initial tumor regressions following this therapy in ''hard-to-treat'' cancers such as colorectal cancer and malignant melanoma, in most instances remissions were not durable. A more sophisticated approach in which tumor-infiltrating lymphocytes (TIL) are obtained, IL-2

Tab. 6 Disease correlates and possible scope for therapeutic/clinical intervention using interleukin inhibitors.

Interleukin	*Disease correlates*	*Possibilities for therapeutic/ clinical intervention*
IL-1	– Gram-negative septacemia,	IL-1ra, soluble IL-1R (other anti-endotoxic shock, hypotension inflammatory agents, e.g. anti-TNFα)
	– Rheumatoid arthritis	As above
	– Multiple sclerosis	,,
	– Kawasaki syndrome (inflammation of veins)	,,
	– Myeloid leukemia	,,
	– Insulin-dependent diabetes mellitus (IDDM)	,,
IL-2	– Lymphoid leukemia	Soluble IL-2R (also anti-TNFα antibody)
	– Systemic lupus erythematosus (SLE)	,,
	– Graft-versus-host disease	,,
IL-3	– Cerebral malaria	Anti-IL-3, anti-GM-CSF, anti-IFNγ
IL-4	– Allergy/asthma	Anti-IL-4, soluble IL-4R
	– IDDM	,,
	– Blepharitis (inflammatory eye lesion)	,,
IL-5	– Allergy/asthma	Anti-IL-5
	– Eosinophilia	,,
IL-6	– Gram-negative septicemia	IL-1ra, soluble IL-1R, anti-TNFα
	– Multiple myeloma	Anti-IL-6, soluble IL-6R
IL-7	– Lymphoid leukemia	Anti-IL-7, soluble IL2R
IL-8	– Psoriasis	Signal transduction inhibitors
	– Erythroderma	,,
IL-10	– Burkitt's lymphoma	Anti-IL-10
	– Malignant B-cell lymphomas in AIDS patients	,,
IL-11	– Megakaryocytic leukemia	Anti-IL-11
IL-12	– Multiple sclerosis	Anti-IL-12
	– Autoimmune diseases	,,
IL-20	– Psoriasis	Anti-IL-20

activated and expanded *ex vivo*, and then reinfused back into the patient with the expectation that the TIL would home back into tumors has shown some promise, but again is complicated by side effects and less-than-durable responses. Novel gene therapy strategies involving the transduction of patients' lymphocytes or fibroblasts with the IL-2 gene leading to constitutive IL-2 production are now being tested.

So far, other interleukins despite their proven immunoregulatory activities *in vitro*, have not yet found much favor among clinicians for the treatment of human diseases. IL-1, for example, has been shown to enhance cellular proliferation and immune responses, but given in high-dose schedules it is probably too profoundly toxic for safe use. Similarly, IL-4 can act as a stimulator of lymphocytes, but its augmentation of IgE secretion and thus the potential for inducing allergic responses may disqualify it from being used clinically.

IL-12 has been proposed as an antitumor agent, but has proved to be quite toxic when administered systemically to cancer patients.

In patients with chronic disease, the presence of certain interleukins and their potential involvement in inflammatory and degradative processes suggests that countering their activities could produce clinical benefits. For example, IL-1 is frequently found in the synovial fluids of RA patients and is quite possibly associated with inflammatory symptoms. Thus, intervention using anti-IL-1 antibodies, IL-1ra, or soluble IL-1R is suggested as a therapeutic approach for RA. For autoimmune diseases such as type 1 diabetes and multiple sclerosis, a similar strategy employing IL-1 antagonists is also suggested. These antagonists could additionally be potentially useful in the treatment of acute illness, for example, bacterial sepsis and shock, as well as perhaps in other conditions such as asthma and acute respiratory distress syndrome (ARDS). So far, clinical phase II trials of IL-1ra in sepsis and RA patients have led to encouraging results and, although IL-1ra was administered in high doses, there were few, if any, side effects.

In several types of hematological malignancies, tumor cells secrete interleukins or other cytokines that may act as autocrine growth factors. For example, IL-2 and IL-7 may be produced by lymphoid leukemia cells, IL-6 by multiple myeloma cells and IL-10 by B-lymphoma (e.g. Burkitt's lymphoma) cells. Such interleukin production therefore suggests a case for investigating whether antagonists of these interleukins would inhibit tumor cell proliferation. There is as yet little clinical work done in the cancer area with interleukin antagonists, and it will be for future clinical trials to determine if they will be successful.

8 Concluding Remarks

Interleukin biology is highly complex due to biochemical redundancy, pleiotropic activities, and the numerous interactions among interleukins themselves and with other biological effector molecules. While some biological activities of individual interleukins shown *in vitro* can be demonstrated *in vivo*, there remain questions about types of expressing and responding cells, sites, levels and duration of expression, developmental stages, and genetic background. Advances in molecular genetics, for example, knockout mice, have provided means for identifying physiological roles for some interleukins, but in most instances it is still not certain that such roles can be compensated for by other interleukins or cytokines, or how such roles are integrated within the host intercellular communication network as a whole. The present fragmentary evidence for defined physiological roles for the majority of interleukins remains an obstacle for translating the activities of these powerful biological molecules into clinically useful treatments of human diseases.

Primary Literature 179

Keywords

Adjuvant
Natural or chemical substance that enhances antigen-stimulated antibody production by B cells and/or activation of T cells.

Antigen
Foreign substance that can stimulate a specific immune response, usually specific antibody; specific determinants on the antigen that are bound by the antibody are known as epitopes.

Live Vaccine
Replication-competent viral or bacterial vaccine; either an attenuated form of a natural infectious agent or a recombinant agent expressing a foreign gene.

Neutralizing Antibody
Antibody to the surface protein of virus particles that renders the virion noninfectious.

Seropositive versus Seronegative
Presence of antibody to a specific pathogen in the serum due to past infection or immunization (seropositive) versus lack of antibody to a specific pathogen in the serum because of no past infection or immunization.

Structural versus Nonstructural Protein
Viral protein species present in the virion (structural) versus viral protein species synthesized in a virus-infected cell but not incorporated into the virion, such as viral DNA polymerase of herpesviruses.

Subunit Vaccine
Purified component of an infectious agent that is incapable of replication in the host but can stimulate a protective immune response; for viruses, natural or recombinant protein.

Virion
Complete infectious virus particle.

Classical live-attenuated vaccines were developed several decades ago for two clinically important human herpesviruses, varicella-zoster virus and human cytomegalovirus. The varicella vaccine has been licensed for immunization of normal children in Japan, Korea, and the United States for a number of years. In contrast, live-attenuated cytomegalovirus has only been tested in a limited number of studies of organ transplant recipients and healthy adult volunteers, and has not yet been considered for licensure. A number of experimental cytomegalovirus vaccines have been developed using molecular biology and recombinant DNA technology, because of theoretical concerns about the long-term safety and effectiveness of the currently available live cytomegalovirus vaccines. Some of the same techniques are also being applied to varicella-zoster virus to develop improved vaccines that could supplement or replace the current varicella vaccine or provide protection against viral reactivation and zoster. The major emphasis of high-technology vaccine development has been on the viral glycoproteins because they are the targets of neutralizing antibody, and includes both recombinant protein subunit vaccines and live-recombinant virus vaccines. Other virion and nonstructural viral proteins are also being considered as immunogens for cytotoxic T-cell responses.

1
Introduction to Human Cytomegalovirus and Varicella-zoster Virus

1.1
Human Diseases from Primary and Recurrent Infection

Varicella-zoster virus (VZV) and human cytomegalovirus (CMV) are both human members of the family *Herpesviridae*, and the vast majority of humans have been infected with both CMV and VZV by the time they reach adulthood. Along with the six other human members, such as herpes simplex virus (HSV) types 1 and 2 and Epstein–Barr virus, these viruses have a common clinical feature of viral latency and reactivation following primary virus infection. Medical complications of reactivation are most severe in immunodeficient or immunosuppressed individuals.

VZV is the cause of the common childhood illness known as chickenpox or varicella, and this disease is characterized by a distinct vesicular rash on the trunk, head, and limbs. VZV is a highly contagious virus, easily spread by respiratory secretions of infected individuals several days before the appearance of skin lesions. Complications of varicella include pneumonia, secondary bacterial infections, and inflammation of the brain, known as encephalitis. These complications may occur in persons with normal immune function and may be life-threatening, but are even more common and serious in immunocompromised persons. Prior to introduction of the varicella vaccine in the

United States, there were approximately 4 million cases of varicella each year in children, 11 000 hospitalizations, and 100 deaths each year, with half of the deaths in children and half in adults infected for the first time with VZV.

Passive immunization with high-titer human antibody against VZV, known as varicella-zoster immune globulin (VZIG), and antiviral therapy with acyclovir, an antiviral drug that inhibits the viral DNA polymerase, can prevent or significantly reduce disease if administered within a few days after exposure to VZV.

The same virus also causes the disease known as shingles or herpes zoster, which is most common in the elderly. This disease results from reactivation of the virus that has been latent in sensory ganglia for decades, with the skin lesions and accompanying pain usually localized to an area of skin innervated by a specific sensory ganglion. The major complication of herpes zoster is the ''postherpetic neuralgia'', which may persist for months in elderly patients. Specific antiviral chemotherapy or passive immunization with VZIG is much less effective in treating reactivated, secondary VZV infection compared to primary infection and varicella.

In contrast to chickenpox/varicella in nonvaccinated children, most primary CMV infections of children or young adults are mild or inapparent, with a mononucleosis-like syndrome being one of the more common symptomatic outcomes in healthy young adults. Past infection with CMV, whether asymptomatic or symptomatic, is indicated by the individual's seropositivity in a laboratory assay for anti-CMV antibody. The site of viral latency following primary CMV infection is not as well characterized as for VZV, but presumably involves white blood cells known as monocytes and polymorphonuclear leukocytes. Serious infections are limited to two major groups: infants infected during pregnancy when virus from the infected mother crosses the placental and infection or reactivation in immunocompromised persons such as immunosuppressed transplant recipients or persons with AIDS. An estimated 1% of all newborns have congenital CMV, but less than 1/10th of these CMV-infected newborns have serious, symptomatic infection at birth. Up to 15% of the congenital infections that are asymptomatic at birth may have later neurological sequelae, especially hearing defects. Intrauterine infection of the fetus during the primary infection of the mother, as compared to reinfection or reactivation in the CMV-seropositive mother, carries the highest risk of serious disease and involves multiple organ systems. The virus is commonly spread among children in preschool and day-care centers because the virus is shed in saliva and urine of asymptomatic children, and it can also spread to CMV-seronegative females of childbearing age who work in these centers or have a child in preschool or day care.

Similarly, the risk of serious and life-threatening CMV disease in immunosuppressed recipients of kidney or liver transplants is lower for seropositive persons undergoing CMV reactivation or reinfection versus seronegative persons acquiring primary CMV infection from the transplanted organ. For CMV-seronegative patients who will be receiving organ transplants from CMV-seropositive donors, initiation of antiviral therapy prior to the transplant can reduce the severity of CMV infection transmitted from the donor tissue. Reactivation of CMV in seropositive patients undergoing bone marrow transplantation or in patients with human immunodeficiency virus and AIDS is also a significant and

sometimes life-threatening disease involving the lungs, liver, or eyes and requires antiviral therapy. The drug of choice is ganciclovir, a compound that inhibits CMV replication by specifically inhibiting the viral DNA polymerase, but can often display significant toxicity.

1.2 Naturally Acquired Protective Immunity

The acquired immunity to CMV following primary infection is typically sufficient to prevent disease in immunocompetent individuals. However, asymptomatic reinfection with different antigenic strains of CMV or reactivation of latent CMV can occur in healthy, CMV-seropositive adults. The antibody and cytotoxic T-cell responses induced by prior CMV infection of females appear insufficient to prevent virus reactivation during pregnancy and congenital infection, but the resulting congenital infections are almost always asymptomatic. Transplacental antibody can also protect newborns and infants from infection or disease after birth until this maternal antibody disappears from circulation.

Immunocompetent children and adults acquire life-long immunity to varicella/chickenpox following this initial infection with VZV, even though the viral genetic information persists in a latent form in nerve tissue known as sensory ganglia. Specific antibody capable of neutralizing virions can be highly protective and can prevent initial infection with VZV, as demonstrated by the protective effects of maternally acquired antibody in preventing varicella/chickenpox in most infants less than 12 months of age. This antibody is transported across the placenta from mother to fetus late in pregnancy and is a natural form of passive immunization against a large number of infectious organisms. Specific cytotoxic T-cell responses are necessary in addition to neutralizing antibody in controlling infection and limiting disease once the virus infection has occurred. These acquired cytotoxic T-cell responses to VZV proteins are essential in preventing or delaying reactivation of latent virus, consistent with the highest incidence of zoster/shingles in the elderly with a natural decrease in the activity of the immune system.

1.3 Efficacy of Live-attenuated Varicella Vaccine in Preventing Chickenpox

The most commonly used varicella vaccine is a live-attenuated VZV strain that was developed in the 1970s from a human clinical isolate of virus from a patient with typical varicella (Table 1). Long-term propagation and multiple passaging of this Oka strain in human diploid fibroblast cell culture led to virus that replicated better in cell culture but was attenuated for replication and pathogenicity in humans, thereby causing infection without disease in most healthy persons when administered by intramuscular or subcutaneous infection. The licensed Oka vaccine strain of VZV can be distinguished from corresponding clinical isolates of VZV on the basis of restriction endonuclease analysis of the viral DNA genome. In addition, determination of the complete DNA sequences of the Oka vaccine virus and its parental virus has recently been completed to allow detailed comparisons and identification of specific gene alterations responsible for the *in vivo* attenuation of the vaccine strain.

Extensive studies of the varicella vaccine in large numbers of healthy children have demonstrated a high degree of safety and

Tab. 1 Important events in the history of varicella vaccine.

Year	*Event*
1974	Development of live-attenuated Oka-strain vaccine in Japan
1979	Initiation of large-scale human trials of Oka varicella vaccine in United States
1995	Licensing of Oka varicella vaccine in United States for healthy children aged 12 months and older and in VZV-seronegative adults
1995	First use of Oka varicella vaccine as live-recombinant vaccine (R-Oka) for protection against other human viruses in animal clinical trials
1996	First human clinical trial of heat-inactivated Oka vaccine in United States for VZV-seropositive adults aged 55 years and older, to decrease incidence and severity of zoster
1998	Initiation of "Shingles Prevention Study," a large-scale clinical trial in United States of live-attenuated Oka vaccine for VZV-seropositive adults aged 55 years and older to decrease the incidence and severity of zoster
2002	Completion of the DNA genome sequences of the Oka vaccine and its parental virus, for mapping of potential attenuation mutations

efficacy in inducing neutralizing antibody to VZV and protection from varicella disease and complications. Approximately 90% of VZV-seronegative healthy children and adults who received a single dose of Oka varicella vaccine in prelicensure clinical trials were protected from illness when naturally exposed to VZV, and essentially all of those vaccinated individuals who did have "breakthrough" varicella after natural exposure to VZV were protected from severe disease. Several studies of varicella outbreaks in preschool and day-care centers since the Varivax (Merck & Co.) vaccine was licensed in the spring of 1995 suggest that the level of protection against varicella in some populations may be much lower than 90%, especially if the children were immunized at 12 months rather than at 15 to18 months of age, but the disease in vaccinated children was milder than in unvaccinated children in the same outbreak. Detailed clinical studies indicate that there is an inverse relationship between the titers of anti-VZV antibody at six weeks postvaccination and the long-term incidence of "breakthrough" varicella, so that specific immunity induced by the vaccine does correlate with protection. The Oka varicella vaccine has not been licensed for immunocompromised children who are most at risk for dangerous disease, although these children could benefit most from the varicella vaccine. The live-attenuated varicella vaccine is somewhat less effective in this population and may actually cause a mild form of varicella.

A second generation of the Oka/Merck varicella vaccine, known as Varivax II, has the same safety and efficacy characteristics of Varivax, but has the advantage of being refrigerator-stable. A similar vaccine has been developed by SmithKline Beecham Biologicals and is known as VARILRIX. There are incentives to develop safer alternatives to these current live-attenuated vaccines because of the ability of the Oka vaccine virus to establish latent infection and subsequently reactivate, and because of the unknown duration of immunity from a single childhood immunization compared to infection

with "wild-type" virus. Two other theoretical concerns with live-attenuated human viruses are potential reversion to virulence during replication in humans and potential oncogenicity in humans. Although the former phenomenon clearly occurred in another human viral vaccine, the live-oral Sabin polio vaccine, there has been no demonstration of similar reversion with the Oka varicella vaccine. Even though several other human herpesviruses are associated with specific human cancers, such as B-cell lymphomas and nasopharyngeal carcinoma with Epstein–Barr virus and Kaposi's sarcoma with human herpesvirus-8, there is no evidence for oncogenicity associated with either natural infection by wild-type VZV or immunization with the live-attenuated varicella virus.

1.4 Vaccine Strategies to Prevent Congenital CMV and Disease in Immunocompromised Adults

The primary target for a safe and effective CMV vaccine is CMV-seronegative females of childbearing age, to prevent symptomatic congenital infection. Another target is CMV-seronegative children or adults who are immunocompromised and at greater risk of CMV disease. Attenuated and laboratory-adapted strains of CMV were developed in the 1970s by the same procedures as those used for the Oka varicella vaccine. One of these, the Towne strain, has been clinically tested in humans, but has not been shown to be effective in preventing primary infection with VZV. The Towne strain may be too highly attenuated, as suggested by the fact that experimental infection does not result in latent infection with potential reactivation.

A number of alternate vaccine strategies are being developed for CMV and also for improved and safer VZV vaccines, on the basis of biochemical and immunological knowledge of the important viral protein components of these viruses and the viral genes encoding these potential vaccine components. One major and current approach for CMV vaccines is the production of recombinant protein subunit vaccines in recombinant bacteria, insect cells, or mammalian cell culture. A second major approach is the production of recombinant viruses that express the CMV gene and can be used as live-recombinant vaccines, including recombinant vaccinia and canarypox viruses and adenoviruses. A third approach is the creation of less-attenuated and possibly more-immunogenic live-attenuated CMV vaccines by constructing genetic chimeras between the Towne strain and a virulent strain. Finally, the newer technology of plasmid DNA vaccines is being applied to CMV and other human herpesviruses.

1.5 Vaccine Strategies to Prevent Zoster in the Elderly and Immunocompromised Adults

Because the time interval between varicella and zoster/shingles can be six decades or longer and correlates with age-induced decreases in immune function, it may be worthwhile to stimulate and enhance cellular immunity against VZV in seropositive adults. This immunization of individuals who have already been infected and still have the virus in the latent form is classified as "therapeutic" immunization, in contrast to the typical "prophylatic" immunization of uninfected individuals with licensed human viral vaccines. One strategy is to immunize seropositive adults with the same dose as children or higher doses of the live Oka varicella vaccine, and this is currently being tested in a large-scale,

long-term clinical trial. In seropositive but immunocompromised individuals, such as candidates for transplantation and immunosuppression, inactivated varicella virus or recombinant protein subunit vaccines may be safer alternatives even though they are generally less effective in stimulating cytotoxic T cells.

2 Virion Structure and Composition

All of the members of the human herpesvirus family have a common structure for the virus particle, or virion, as shown in Fig. 1. From the inside to the outside, there are four structures: an inner core containing the viral genetic information (DNA genome) associated with viral protein, a protein shell with icosahedral symmetry known as an icosahedral capsid, an amorphous layer containing viral proteins known as the tegument or matrix, and a surface envelope composed of a cell-derived lipid bilayer and multiple species of viral glycoprotein. The single-letter alphabetical nomenclature for individual envelope glycoproteins is based upon homology to envelope glycoproteins of herpes simplex virus-1 (HSV-1). The envelope is the most fragile component of the virion, and removal or destruction of the envelope with detergents or organic solvents such as ether or chloroform renders the virion noninfectious. The corresponding capsid, tegument/matrix, and envelope glycoproteins of CMV and VZV serve similar functions in virus attachment to cells, intracellular replication, and virus assembly and egress. However, the corresponding CMV and VZV proteins have distinct amino acid sequences and can be distinguished by reactivity with VZV-specific versus CMV-specific antibody.

2.1 Viral DNA Genomes and Specific Gene Sequences for Recombinant Vaccines

The viral genome for all herpesviruses is a linear molecule of double-stranded DNA. This genome encodes all these virion-associated structural proteins as well as additional nonstructural viral proteins that may function as intracellular enzymes and regulatory proteins. The 230 kb DNA genome of CMV is among

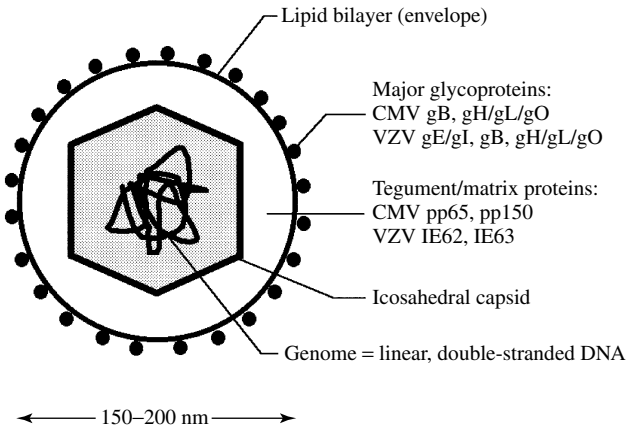

Fig. 1 Structure and composition of CMV and VZV virions.

the largest of all human viruses. The complete nucleotide sequence has been determined for both the AD-169 and Towne laboratory-adapted strains, and this sequence contains approximately 200 distinct open reading frames (ORFs) capable of coding for approximately 200 distinct polypeptides. In contrast, the VZV DNA genome is 125 kb in length, and the complete nucleotide sequence determined for several strains predicts 71 ORFs for potential viral polypeptides. As shown in Fig. 2, herpesviral genomes have the unusual characteristic of repeated DNA sequences at one or both ends and at an internal site (TR and IR), which results in recombinational inversion of unique long (U_L) and/or unique short (U_S) sequences during intracellular DNA replication. Each of the four isomeric forms of the linear DNA genome for CMV and the two isomers for VZV can be packaged with equivalent efficiency into new virions and exhibit similar infectivity. Determination of the location and nucleotide sequences of individual genes in the large DNA genomes of VZV and CMV (Fig. 2) has permitted detailed structural analysis of the deduced amino acid sequences for immunologically important viral proteins. This has greatly facilitated expression of these genes into recombinant protein or inclusion into live-recombinant vaccines.

2.2 Immunogenic Proteins for Eliciting Neutralizing Antibody

A general principal of viral immunology is that surface proteins of the virion are the target antigens for protective antibody responses. In the case of lipid-enveloped

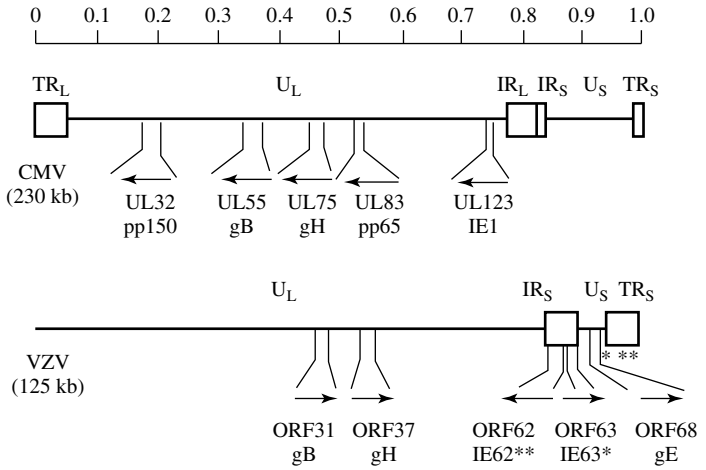

Fig. 2 Structure of the DNA genome for CMV and VZV and location of genes for important viral antigens. Only one of four possible isomers for CMV and one of the two possible isomers for VZV are displayed. The top scale corresponds to genetic map units (0.0–1.0). Open boxes represent inverted repeat sequences at the ends of the unique long (U_L) and unique short (U_S) genome segments, and arrows indicate the orientation of coding sequences, which are identified by gene number and gene product. The single and double asterisks indicate the positions of inverted duplication of *IE62* and *IE63* genes at the right end of the VZV genome.

viruses such as VZV and CMV, these neutralizing antibodies are elicited and bound by the envelope glycoproteins, whereas antibody produced to internal virion proteins such as tegument and capsid proteins is not protective and is only useful for confirming VZV or CMV infection. Helper T-cell responses are necessary for production of antibody against protein antigens, so that T-cell responses to both surface and internal virion proteins can have an indirect role in antibody production.

The major glycoprotein species for CMV are gB and the gH/gL/gO heterotrimer, and the major species for VZV are the gE/gI heterodimer, gB, and the gH/gL/gO heterotrimer (Fig. 1). CMV and VZV gB glycoproteins may also exist in oligomeric forms in their native conformation on the surface of the virion, either as a dimer or a tetramer. The characteristics of these viral gene products are summarized in Table 2. The original electrophoretic analyses of purified CMV and VZV detected a larger number of electrophoretically distinct envelope glycoproteins, but subsequent immunological analyses with monoclonal antibodies demonstrated that these multiple species actually

Tab. 2 Characteristics of major immunogenic proteins of CMV and VZV.

Protein (gene)	*Viral function*	*Immunogenicity*
CMV gB (UL55)	Most abundant glycoprotein in envelope; virion fusion and penetration into cell	Principal target of neutralizing antibody, and target for helper and cytotoxic T cells
CMV gH (UL75)	Second most abundant glycoprotein in envelope, oligomer with CMV gL and gO; fusion	Target of neutralizing antibody and helper/cytotoxic T cells
CMV pp65 (UL83)	Major component of tegument; phosphoprotein with protein kinase activity and role in intracellular regulation	Principal target for helper and cytotoxic T cells
CMV pp150 (UL32)	Second most predominant component of tegument; phosphoprotein	Significant target of helper and cytotoxic T cells
CMV IE1 (UL123)	Nonstructural protein; immediate-early protein important in regulation	Significant target for cytotoxic T cells
VZV gE (ORF68)	Most abundant glycoprotein in envelope; oligomer with gI	Major target of neutralizing antibody
VZV gB (ORF31)	Second most abundant envelope glycoprotein; virion entry and fusion	Target of neutralizing antibody
VZV gH (ORF37)	Glycoprotein component of envelope; oligomer with VZV gL and gO	Target of neutralizing antibody
VZV IE62 (ORF62)	Major component of tegument; immediate-early regulatory protein with role in replication; major altered gene product in Oka vaccine vs parental virus strain	Major target of cytotoxic T cells
VZV IE63 (ORF63)	Component of tegument; immediate-early protein with regulatory role in intracellular replication	Major target of cytotoxic T cells

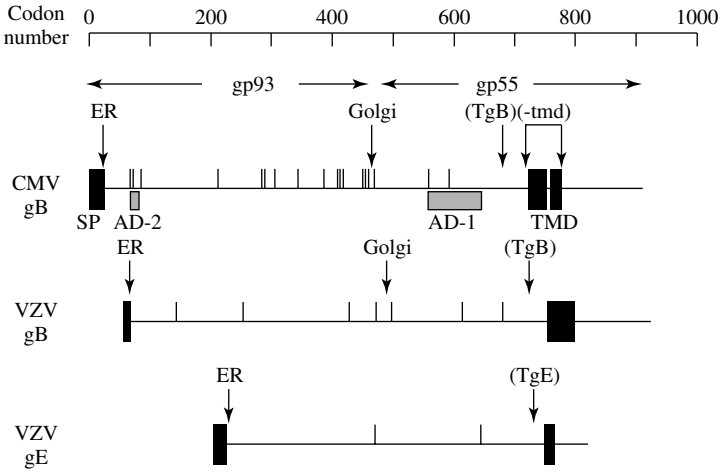

Fig. 3 Linear structure of major CMV and VZV envelope glycoproteins. These diagrams are based upon the derived amino acid sequences from the nucleic acid sequences of the corresponding genes indicated in Fig. 2. The solid black boxes represent hydrophobic domains: amino-terminal signal peptide (SP) and membrane-anchor/transmembrane domain (TMD). Short vertical lines indicate the positions of potential asparagine-linked oligosaccharides. Vertical arrows indicate the positions of cotranslational cleavage by the cellular signal peptidase (ER), posttranslational cleavage of gB into mature subunits (gp93 and gp55 for CMV) by a cellular endoprotease (Golgi), and removal of the membrane-anchor/TMD by gene truncation after codon 680 of CMV gB (TgB) or codon 511 of VZV gpE (TgpE). Another recombinant and genetically modified form of gB lacks the transmembrane-anchor domain (-tmd) but maintains the carboxy-terminus of full-length glycoprotein. Crosshatched rectangles below the CMV gB polypeptide indicate the positions of an amino-terminal linear neutralization epitope in the gp93 subunit (antigenic domain-2 = AD-2) and an immunodominant linear neutralization domain in the gp55 subunit (antigenic domain-1 = AD-1).

represent a more limited set of gene products with heterogeneity due to oligosaccharide modifications and posttranslational proteolytic cleavage. For example, the CMV *gB* gene encodes a precursor glycoprotein of approximately 130 to 160 kDa and processed subunits of 93 to 116 kDa and 55 kDa (gp93 and gp55 proteins in Fig. 3). These glycoproteins contain multiple asparagine-linked oligosaccharides that are added and processed by host cell machinery, and some of the proteins may also contain some serine- or threonine-linked oligosaccharides. Both viruses contain additional minor glycoprotein species, but their contribution to the induction of neutralizing antibody in natural CMV and VZV infections is less well characterized.

The amino acid sequences deduced from the DNA gene sequences (Fig. 2) for the predominant CMV and VZV glycoproteins are indicative of type I integral membrane proteins, with an amino-terminal hydrophobic signal peptide (SP) necessary for transport of the protein into the

lumen of the endoplasmic reticulum (ER) and another hydrophobic, transmembrane domain (TMD) closer to the carboxy terminus, which functions as a membrane anchor (Fig. 3). More detailed analysis of these amino acid sequences for CMV gB suggests that the first of two hydrophobic peptides is actually a fusion domain on the noncytoplasmic side of the membrane and the second is the actual transmembrane anchor. The removal of the SP is usually a cotranslational event or posttranslational event in the ER, whereas the cleavage of CMV and VZV gB into mature subunits occurs late in processing after transport from the ER to the Golgi membranes. The positions of potential sites for cotranslational addition of asparagine-linked oligosaccharides in the ectodomain between the SP and TMD correspond to Asn-X-Ser/Thr, where X is any amino acid except proline. CMV gB, especially the gp93 subunit, is among the most highly glycosylated of all viral glycoproteins, with approximately 15 asparagine-linked oligosaccharides in the gp93 subunit compared to only 4 potential oligosaccharides on the corresponding subunit of the VZV gB glycoprotein and 2 potential oligosaccharides in the entire ectodomain of VZV gE. These multiple oligosaccharides may help the virus evade host immune responses by preventing access of neutralizing antibodies to antigenic determinants on the viral polypeptide. Multiple cysteine residues in the ectodomain of these major VZV and CMV glycoproteins form intramolecular disulfide bonds, which are presumed to be very important in the overall structure and expression of antigenic determinants in the native molecules.

In contrast to typical cellular genes for membrane glycoproteins, there are no intervening sequences (introns) within the coding sequences for the CMV and VZV glycoproteins, so that DNA fragments can be directly isolated by restriction endonuclease digestion from viral genome DNA, rather than having to isolate viral mRNA and then produce complementary DNA (cDNA) prior to recombinant expression. The important linear and continuous neutralizing epitopes of the CMV gB protein have been specifically mapped using synthetic or recombinant peptides on the basis of the deduced amino acid sequence: the immunodominant domain, known as *antigenic domain 1* (AD-1), is within the gp55 subunit and an additional epitope is located near the amino terminus of the gp93 subunit, known as *antigenic domain-2* (AD-2) (Fig. 3). Discontinuous and conformational epitopes, unlike continuous and linear epitopes, cannot be duplicated by synthetic or recombinant peptides, and are usually lost after protein denaturation or protein misfolding. Neutralization epitopes for the other CMV and VZV envelope glycoproteins are less well characterized.

2.3 Immunogenic Proteins for Stimulating Cytotoxic T cells

Virus-specific cytotoxic T cells are important in recognizing and destroying virus-infected host cells, so that these cellular factories for production of new virus are shut down. Cytotoxic T cells have specific T-cell receptors on their surface that recognize peptide fragments of foreign proteins that were synthesized in the target cells, proteolytically processed, and transported to the surface in a complex with class I major histocompatibility antigens. These viral proteins can be either structural proteins that get assembled into virions (Fig. 1) or nonstructural viral proteins present only in infected cells.

Although the gB and gH envelope glycoproteins of CMV can be targets of cytotoxic T cells, the major target for cytotoxic T cells in infected humans is the pp65 tegument protein. Other important proteins for CMV-specific cytotoxic T-cell responses include the pp150 tegument protein and the IE1 immediate-early and nonstructural protein. IE1 is the first viral protein synthesized after reactivation of CMV from latency. The IE1 protein is encoded by one of the few CMV genes with intron sequences and spliced mRNA, with the second and third exons encoding short peptides also present at the amino terminus of several other IE proteins and the fourth exon encoding the unique immunodominant peptide sequences of IE1.

The relative importance of glycoproteins for neutralizing antibody and tegument proteins for cytotoxic T cells is also characteristic of VZV: two immediate-early proteins that are synthesized early in infection and present in the tegument layer of virions are the major targets for VZV-specific cytotoxic T-cell responses. One of these, IE62, has a number of amino acid mutations in the attenuated Oka varicella vaccine strain compared to the parental virus strain, although differences in IE62-specific cytotoxic T-cell responses in humans with natural VZV infection versus immunization with the Oka varicella vaccine have not been described.

3 Protein Subunit Vaccines

Because of potential concerns with the long-term safety and effectiveness of live-attenuated herpesvirus vaccines, there are major efforts under way in developing and testing protein subunit vaccines for CMV, and more limited studies are also under way for VZV. Nonreplicating and inactivated viral vaccines have the major advantage of safety compared to live-attenuated viral vaccines, but the disadvantage of requiring multiple vaccine doses to obtain helper T-cell responses and levels of antibody production by B cells that are comparable to those obtained with a single inoculation of a live-attenuated vaccine. In addition, these nonreplicating protein-based vaccines require a chemical or biological adjuvant. Physical or chemical inactivation of whole virus particles has been used in the production of a number of licensed human vaccines, including those for rabies, polio, and hepatitis A viruses. However, protein antigens purified from virions can be just as effective in stimulating the production of neutralizing antibody, while possessing fewer side effects or biosafety risk from residual infectious virions or viral genomes. With modern recombinant DNA technology, immunogenic viral proteins can be produced in mass quantities at lower expense than from virions or virus-infected mammalian cell cultures.

3.1 Natural and Recombinant CMV gB Protein

Nonrecombinant gB protein can be isolated and purified from the envelope of virions, cell membranes of CMV-infected human diploid fibroblast cells, or cell-associated subviral particles known as *dense bodies*. These dense bodies, so named because of their electron-dense appearance in electron microscopy of thin sections of infected cells, contain the viral envelope and tegument proteins, but lack the capsid and viral DNA genome. In addition, a number of recombinant techniques are

Tab. 3 CMV gB antigen and subunit vaccines.

Source of Protein	***Characteristics of Protein (Fig. 3)***
Virions purified from CMV-infected cells	Full-length glycoprotein, cleaved by cell protease into gp93/gp55 subunits
Envelope glycoprotein from CMV-infected cells	Full-length glycoprotein, mixture of uncleaved and gp93/gp55 subunits
Dense bodies purified from CMV-infected cells	full-length glycoprotein, mostly uncleaved
Recombinant *E. coli* bacteria	Nonglycosylated polypeptides containing either AD-1 or AD-2 sequences
Recombinant adenovirus-infected human epithelial cells	Full-length glycoprotein, mostly uncleaved
Recombinant baculovirus-infected insect cells	Full-length or truncated, soluble glycoprotein [TgB], mostly uncleaved
Recombinant vaccinia virus–infected cells	Full-length glycoprotein, mostly uncleaved
Recombinant, genetically modified Chinese hamster ovary (CHO) cells	Transmembrane anchor-deleted [gB(-tmd)], soluble and secreted glycoprotein

being used to produce full-length and genetically deleted or truncated forms of gB from UL55 gene sequences (Table 3).

A number of plasmid vectors are available for high-level, inducible expression of eukaryotic gene sequences in recombinant *E. coli* bacteria as fusion proteins or nonchimeric polypeptides representing potential antigenic domains of viral proteins. There are several potential problems in expressing viral glycoprotein genes in immunogenic protein with the same neutralizing epitopes as the natural protein, including lack of addition of asparagine-linked oligosaccharides in bacteria, and potential toxicity of the hydrophobic amino-terminal SP of eukaryotic proteins to bacteria. A cell lysate of recombinant *E. coli* containing a nonglycosylated, SP-deleted form of CMV gB was able to induce low levels of neutralizing antibody in mice but lacked some of the important antigenic determinants of the native CMV gB. A recombinant *E. coli*-derived polypeptide representing AD-1 of CMV gB has the correct antigenic structure if a key intramolecular disulfide bond is present, even though the polypeptide lacks the two oligosaccharide chains of the native protein (Fig. 3).

Recombinant baculovirus-infected insect cells have become a popular and economical system for producing large quantities of glycosylated protein antigens. The major strategy in the construction of recombinant baculoviruses is the replacement of coding sequences of the polyhedrin (PH) protein with coding sequences of the desired foreign protein, because the polyhedrin gene is expressed in huge quantities late in viral infection but is unnecessary for virus replication in cell culture. The initial step in the construction of recombinant baculoviruses is to clone the viral coding sequences into an *E. coli* bacterial plasmid that contains a multiple restriction site for cloning downstream of the polyhedrin promoter and is flanked by baculovirus sequences that allow reciprocal recombination with the genome. The *E. coli*

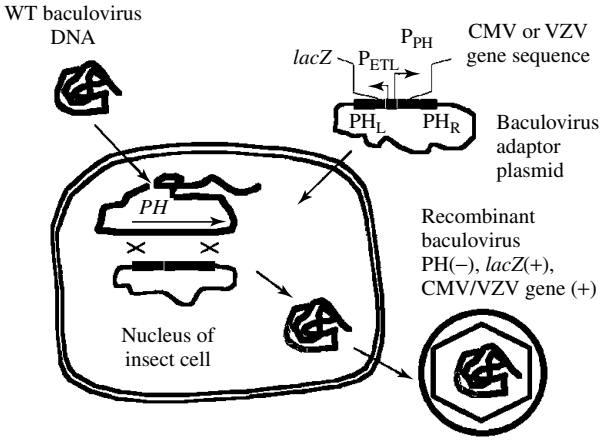

Fig. 4 Production of recombinant baculoviruses to express CMV and VZV glycoprotein genes. This diagram displays the rare reciprocal recombination event that occurs in cells cotransfected with the full-length, wild-type DNA genome and adaptor plasmid DNA containing the foreign herpesviral gene. *PH* refers to the polyhedrin gene, PH_L and PH_R to left and right baculovirus recombination sequences in the plasmid, and P_{ETL} and P_{PH} refer to specific baculovirus promoters for gene transcription. *lac*Z is the coding sequence for the bacterial β-galactosidase protein used in the positive selection of recombinant virus.

β-galactosidase gene (*lac*Z) under control of another baculovirus promoter is also included for positive selection of recombinant virus (Fig. 4). Recombinant baculoviruses are produced by cotransfection of full-length viral genome DNA and the adaptor plasmid containing the herpesviral gene sequences, followed by selection of blue-colored plaques containing rare recombinant viruses that result from intracellular reciprocal recombination.

The major difference in posttranslational processing in insect cells versus mammalian cells is in the final stages of asparaginyl-oligosaccharide processing in Golgi vesicles: high-mannose precursor oligosaccharide structures ($Man_{5-9}GlcNAc_2$-Asn) can be converted into complex, acidic structures [$(NeuNAc \pm Gal\text{-}GlcNAc)_{2-4}Man_3GlcNAc_2(\pm Fuc)$-Asn] in mammalian cells, but are converted into more simple mature structures ($Man_3GlcNAc_2$-Asn) in insect cells. This oligosaccharide difference does not appear to adversely affect the structure and conformation of the polypeptide and may actually make some of the linear or conformational epitopes even more accessible. In contrast, asparagine-linked oligosaccharides in yeast can be processed to large oligomannose structures known as mannan, and this modification can lead to insolubility and loss of antigenic determinants for recombinant glycoproteins.

The glycosylated, full-length gB protein of CMV has been purified from recombinant baculovirus-infected insect cells and demonstrated to induce neutralizing antibodies in mice. Cleavage into gp93

and truncated gp55 subunits is inefficient in the baculovirus-infected insect cells, even when gB proteins are efficiently transported through Golgi membranes. Truncated versions of gB lacking the membrane-anchor and cytoplasmic domain (TgB in Fig. 3) or with more extensive internal deletions in heavily glycosylated domains have also been produced in recombinant baculovirus-infected insect cells, and still maintain the antigenic determinants of both the immunodominant gp55 domain and the amino-terminal gp93 linear neutralization epitope (AD-1 and AD-2 in Fig. 3). The removal of the transmembrane anchor also allows the protein to be secreted from cells in a soluble form that is more easily isolated and purified.

Recombinant viral glycoproteins expressed in mammalian cells are usually similar, if not identical, to the corresponding natural protein from CMV-infected cells with respect to co- and posttranslational modifications and antigenic structure, but this must be balanced with the higher cost of mammalian cell culture compared to the baculovirus-insect cell system. Chinese hamster ovary (CHO) cell lines are commonly used in genetic studies because of the ease of manipulation and growth properties in selective media. Genetically modified CHO cells with recombinant CMV UL55 sequences were used to produce a membrane-anchor-deleted CMV gB subunit vaccine known as *cytomegalovirus glycoprotein vaccine* (Chiron). This gB(-tmd) glycoprotein (Fig. 3) is secreted from the CHO cells as a mixture of cleaved subunits and uncleaved glycoprotein, and this secretion still occurs when the gp93/gp55 endoproteolytic cleavage site is eliminated by site-specific mutagenesis.

3.2 Other Recombinant and Chimeric CMV Proteins

The gH envelope glycoprotein is also a candidate for protein subunit vaccines in combination with gB, rather than being used in place of gB. However, coexpression of the *gL* gene product may be necessary for efficient processing and intracellular transport of gH in recombinant baculovirus-infected insect cells or genetically modified CHO mammalian cells, because gL serves as a protein chaperon in transport from the ER to the Golgi and plasma membranes.

Although recombinant proteins are usually not good immunogens for stimulating specific cytotoxic T cells, a chimeric polypeptide containing an immunodominant peptide from CMV pp65 linked to a nonviral peptide and a chimeric CMV IE1-pp65 protein may both be immunogenic in stimulating both helper T-cell and cytotoxic T-cell responses.

3.3 Recombinant VZV gE, gB, Tegument, and Chimeric Proteins

Truncated and soluble VZV gE and gB glycoproteins have also been expressed as immunogenic glycoproteins in the recombinant CHO mammalian cell or baculovirus-infected insect cell systems (Table 4). Although *gE* (ORF68) and *gI* (ORF67) genes can be coexpressed to produce heterodimers equivalent to the virion glycoprotein, expression of *gI* has not been necessary for efficient production and secretion of soluble and immunogenic gE in CHO cell cultures. A genetically modified CHO cell line was also used to produce a chimeric gE-IE63 protein that combines the neutralizing antibody-inducing properties of gE with the dominant T-cell-inducing properties of the immediate-early

Tab. 4 VZV protein antigens and subunit vaccines.

Source of protein	*Characteristics of protein (Fig. 3 for gE or gB)*
Virions purified from VZV-infected cells	Full-length gE or gB; IE62 or IE63 tegument proteins

Recombinant vaccinia virus–infected cells	Full-length gE, gB, or gH/gL oligomer
Recombinant yeast Ty virus–like particles	Chimeric proteins with fragments of gE

and tegument protein when used to vaccinate guinea pigs.

Another relatively new vaccine technology has been recently applied to immunogenic proteins of VZV: the production of recombinant, hybrid Ty virus–like particles in yeast. These particles are devoid of nucleic acid and contain only the yeast transposon protein modified to contain polypeptide fragments of VZV gE or other viral proteins, so that they are safer than live-recombinant or live-attenuated vaccines but have the potential for stimulating both neutralizing antibody and cytotoxic T-cell responses. Immunization studies in mice and guinea pigs have demonstrated the immunogenicity of these recombinant gE-Ty particles.

4
Live-recombinant Virus Vaccines

Live-recombinant vaccines have the advantage of inducing both neutralizing antibody plus cytotoxic T-cell responses, and single inoculations are usually as effective as multiple doses of a nonreplicating subunit vaccine. The immunogenicity of membrane-anchored versus truncated and soluble forms of viral envelope glycoproteins may vary depending upon the amount of membrane-anchored protein that reaches the cell surface or soluble form that is secreted from cells. Thus, both forms may need to be analyzed for each individual viral glycoprotein species to determine the most immunogenic live-recombinant vaccine. The live-recombinant viral vaccines that have been developed to express CMV or VZV genes are summarized in Table 5. Cell cultures infected with these live-recombinant viruses are important sources of recombinant protein for use in subunit vaccines or immunological assays (Tables 3 and 4).

4.1
Recombinant Poxviruses Expressing CMV or VZV Genes

Vaccinia virus, a member of the poxvirus family, has been extensively developed as a live-recombinant vector over the last two decades because this naturally attenuated virus had been used as a smallpox vaccine in humans for over a century, culminating in the global eradication of smallpox in 1977. Immunization with vaccinia virus had a much higher level of complications

Tab. 5 Experimental live-recombinant vaccines for CMV and VZV.

Gene product	*Recombinant vector*	*Immune response*
CMV gB	Adenovirus	Neutralizing antibody in guinea pigs; gB-specific cytotoxic T-cell response in mice
CMV IE1 (exon 4)	Adenovirus	IE1-specific cytotoxic T-cell response in mice
CMV gB	Canarypox virus	Antibody and cytotoxic T-cell response in guinea pigs; priming and enhancement of antibody response to subsequent CMV (Towne) vaccine in humans
CMV pp65	Canarypox virus	Antibody and cytotoxic T-cell response in humans
CMV gB	Vaccinia virus	Neutralizing antibody in mice
VZV gE or IE62	Herpes simplex virus-1	Antibody response in mice
VZV gE and/or gB	Vaccinia virus	Neutralizing antibody and T-cell response to gE or gB in mice, guinea pigs, or rabbits
VZV gH and gL	Vaccinia virus	Neutralizing antibody to gH in mice and guinea pigs
VZV IE62	Vaccinia virus	T-cell response and protection of guinea pigs against challenge with guinea pig–adapted VZV

than other licensed human vaccines, even in persons with normal immune systems. In the event that smallpox immunization is renewed on a large scale in response to potential use of smallpox in bioterrorism, immunocompromised persons such as transplant recipients and persons infected with human immunodeficiency virus are at especially high risk of serious and life-threatening complications if vaccinated or accidentally exposed by contact with skin lesions of an immunized individual. The Western Reserve (WR) strain has been commonly used in construction of live-recombinant vaccinia viruses and was derived from a human vaccine strain by neuroadaptation in mice. Several more-highly attenuated strains are available that would be safer for production of recombinant vaccinia-derived vaccines for human use. A live-recombinant vaccinia virus expressing the rabies virus glycoprotein gene has been licensed for special use as a rabies vaccine against terrestrial wildlife, including raccoons in the eastern United States and foxes in western Europe.

The construction and isolation of recombinant vaccinia viruses for expression of human viral genes is similar in some respects to the process for recombinant baculoviruses: the foreign gene sequences are cloned downstream of a vaccinia promoter in an adaptor plasmid, and recombinant virus is produced by rare reciprocal recombination and replacement of the vaccinia thymidine kinase (*TK*) gene with the foreign gene plus the *lac*Z indicator gene (Fig. 5). Nonrecombinant, TK-positive virus is negatively selected in the presence of a toxic nucleoside analogue, and recombinant, *lacZ*-positive virus is positively selected by the appearance of

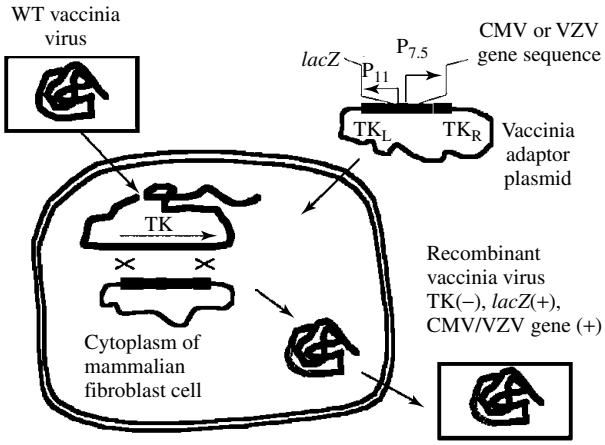

Fig. 5 Production of recombinant vaccinia viruses to express CMV and VZV genes. This diagram displays the rare reciprocal recombination event that occurs in cells infected with wild-type vaccinia virus and cotransfected with adaptor plasmid DNA containing the foreign herpesviral gene. Abbreviations and symbols are the same as those described in the caption to Fig. 4, except that TK refers to the vaccinia thymidine kinase DNA sequences and enzymatic activity, and P_{11} and $P_{7.5}$ refer to vaccinia virus-specific transcriptional promoters.

blue plaques. The vaccinia *TK* gene is unnecessary for virus replication in cell culture, and inactivation of the *TK* gene by this negative selection process further attenuates the vaccinia virus, so that complications in humans with TK-negative virus may be less than the complications in those with wild-type vaccinia virus.

The large vaccinia DNA genome (185 kb) can accommodate at least 25 kb of additional foreign DNA sequences without significant deleterious effects on virus replication, so that multiple foreign virus sequences can potentially be expressed in the same virus, such as both the *CMV gB* (UL55) gene for induction of neutralizing antibodies and the *CMV pp65* (UL83) gene for induction of cytotoxic T cells. Several different recombinant vaccinia viruses have been constructed to express CMV or VZV glycoprotein and tegument genes, and they have been tested in experimental animals (Table 5). These recombinant viruses are also useful for production of recombinant protein in cell culture and for production of specific target cells necessary for assaying virus-specific cytotoxic T cells in cell culture.

An avian poxvirus, canarypox virus (ALVAC), has also been genetically engineered to express human herpesvirus proteins, because the inability to replicate in mammalian cells makes the avian viruses much safer than recombinant vaccinia viruses for use in humans. Pasteur Merieux Connaught has manufactured ALVAC-CMV gB and -CMV pp65 viruses and clinically tested them in CMV-seronegative volunteers (Table 5). Because of the extreme attenuation of canarypox virus in human cells, ALVAC-CMV gB is relatively nonimmunogenic when used alone, and may be best when used in combination with other

vaccines in ''prime-boost'' immunization strategy.

4.2 Recombinant Adenoviruses Expressing CMV Genes

The idea of using live-recombinant adenoviruses as vaccines is based upon the extensive experience of using enteric-coated human adenovirus types 4 and 7 to immunize military recruits for prevention of acute respiratory disease. The enteric coating prevents the virulent adenovirus from replicating in the respiratory tract and causing disease, but allows the virus to replicate in the gastrointestinal tract after uncoating in the stomach, where it induces good systemic and mucosal immunity without causing disease. These vaccines have the additional advantage of inducing mucosal IgA antibody, which can block the virus soon after entrance into the body, rather than just serum antibody, which blocks infection at a later generalized stage.

In contrast to the large capacity of recombinant vaccinia virus for additional foreign DNA, the 36 kb DNA genome of human adenovirus type 5, the type most commonly used in construction of recombinant adenoviruses, can only accommodate approximately 2 kb additional DNA without genetic instability and inefficient genome packaging into the adenoviral icosahedral capsid. Because approximately 2 kb of nonessential *E3* gene sequences can be deleted, foreign gene inserts of 4 kb can be accommodated during the construction of replication-competent recombinant adenoviruses. One method for construction of these recombinant adenoviruses utilizes an adaptor plasmid containing the final 40% of the viral genome, with the foreign coding sequences inserted downstream of the viral E3 promoter (Fig. 6). These recombinant viral sequences are cotransfected or electroporated into human epithelial cells in culture along with an adenoviral DNA fragment containing the first 76% of the genome, and infectious adenovirus is isolated after several days. These E3-deleted recombinant virions are replication-competent, in contrast to the E1-deleted replication-defective recombinant adenovirus vectors used in experimental gene therapy. The essential *E1* gene is located at the left end of the

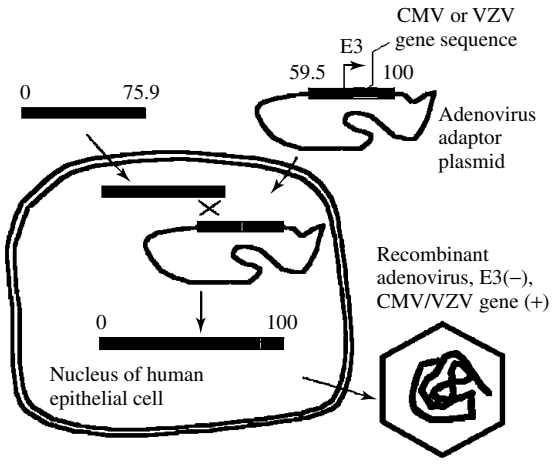

Fig. 6 Production of recombinant, replication-competent adenoviruses to express *CMV* and *VZV* genes. This diagram displays the rare reciprocal recombination event that occurs in cells cotransfected with overlapping fragments of the complete adenovirus DNA genome (0–100 map units), with one plasmid-associated fragment (59.6–100 map units) containing herpesviral gene sequences in place of adenoviral E3 coding sequences downstream of the E3 promoter. The infectious icosahedral virion of the recombinant adenovirus is displayed at the bottom right.

adenovirus genome (map position 1–11 in Fig. 6), and recombinant viruses with this sequence deleted can only replicate in special cell lines that constitutively produce the viral *E1* gene products.

Replication-competent adenoviruses that expressed the full-length *CMV gB* (UL55) gene or part of the *IE1* (UL123) nonstructural gene were capable of eliciting neutralizing antibody and/or cytotoxic T-cell responses following intraperitoneal or intranasal inoculation into experimental animals (Table 5). These immune responses occurred despite the fact that adenovirus infection is incomplete in these nonhuman hosts, presumably because the adenoviral E3 promoter is expressed at an early time after infection even when intracellular replication is incomplete. In related studies with another human herpesvirus, a recombinant adenovirus expressing the *gB* gene of HSV-1 was able to protect mice against a lethal challenge with mouse-adapted HSV-1. Human trials with enteric-coated live-recombinant adenovirus type 5 will be necessary to demonstrate the efficacy of this vaccine strategy for humans.

4.3 Recombinant VZV Expressing Heterologous Viral Genes

To take advantage of the extensive clinical history and relative safety of the Oka varicella vaccine in humans, this live-attenuated virus strain has been modified by recombinant DNA technology to express genes for other protective and immunogenic viral proteins. These include the hepatitis B virus surface antigen, the gD glycoprotein of HSV-2, and the human immunodeficiency virus envelope glycoprotein. These live-recombinant varicella vaccines, known as R-Oka vaccines, have not yet been tested in humans but have been shown to be immunogenic in guinea pigs, an experimental animal that is susceptible to infection by wild-type and attenuated VZV. In the case of the R-Oka-HSV-2 gB vaccine, immunized guinea pigs were protected against a challenge infection by HSV-2. Live-recombinant virus vectors have also been developed for HSV-1, and recombinant HSV-1 expressing *VZV gE* or *IE62* genes has been shown to be immunogenic in mice. One major disadvantage of using live-recombinant vaccines derived from attenuated VZV or HSV is that the immune response to the foreign gene product would be limited and minimal in immunized individuals who had prior immunity to the herpesvirus vector from either natural infection or vaccination.

5 Plasmid DNA Vaccines for VZV and CMV

The most revolutionary development in vaccines against human virus infection and disease utilizes direct inoculation with plasmid DNA containing foreign gene sequences under the control of eukaryotic transcriptional signals, first reported in animal immunization studies with influenza viral genes in 1993. This technology has since been applied to a large number of other viral genes and genes of other infectious agents, and would be most applicable to viral genes that have been shown to induce protective antibody or cytotoxic T-cell responses when expressed by live-recombinant viral vaccines.

The basic requirements for the plasmid DNA vaccines are the same as those for plasmids used for transient gene expression in transfected mammalian cells in culture: upstream promoter and enhancer sequences recognized

Tab. 6 Experimental plasmid DNA vaccines for CMV and VZV.

Gene product	*Immune responses*
CMV gB, TgB, and gB(-tmd) (Fig. 3)	Neutralizing antibody in mice, with higher titers with gB(-tmd) or TgB vs full-length gB; priming for booster immunization with purified gB protein subunit vaccine
CMV pp65	Cytotoxic T-cell response and nonneutralizing antibody
CMV pp65 with kinase-deficient mutation	Cytotoxic T-cell response similar to that with wild-type gene
VZV TgB and TgE (Fig. 3)	Strong neutralizing antibody against gB in mice, but only weak antibody response to gE
VZV gE or TgE	Antibody responses to both in mice, but different antibody classes indicative of Th1 (gE) vs Th2 (TgE) helper T-cell responses
VZV gE and IE62	Antibody and T-cell proliferative responses to both gene products in mice

by host cell transcriptional machinery, coding sequences with in-frame ribosomal initiation and termination codons, and downstream polyadenylation and RNA termination sequences. Routes of inoculation of plasmid DNA in animal studies have included epidermal, intramuscular, mucosal, and intravenous.

These DNA vaccines are safer than live-recombinant vaccines because they do not replicate once they have entered the cell nucleus. Also, the same plasmid DNA vector can be used multiple times with either the same or different foreign gene sequences, without the immunized host developing immunity to the vector. The production and purification of bacterial plasmid DNA is also much less expensive than the purification of protein for subunit vaccines or the production and purification of live-recombinant virus vaccines.

The DNA vaccines designed to prevent primary human CMV infection have employed the coding sequences for the major targets of neutralizing antibody and cytotoxic T cells in humans (Table 6). Plasmid DNA encoding a truncated gB glycoprotein (equivalent to TgB in Fig. 3) was able to induce significant levels of gB-specific neutralizing antibody in a majority of mice after three intramuscular doses, and half of the mice inoculated with a pp65-expressing plasmid developed pp65-specific cytotoxic T-cell responses. In related studies with another human herpesvirus, mice inoculated with a plasmid expressing the HSV-1 gB protein developed high levels of gB-specific antibody and were protected from a lethal challenge with HSV-1.

Current studies with DNA vaccines for VZV (Table 6) have utilized genes encoding full-length or truncated forms of both gE and gB envelope glycoprotein in order to induce neutralizing antibody in mice. Also, immunization with plasmid DNA–containing sequences for IE62 has induced T-cell responses in mice. Similar studies will need to be conducted in guinea pigs because these animals are susceptible to infection with human VZV and they provide an experimental model for directly analyzing whether vaccine-induced immune responses are protective.

Optimization of immune responses to DNA vaccines for VZV or CMV may require a multidose combination of plasmid DNA immunization along with live-attenuated virus or protein subunit vaccines, with initial testing in animals prior to phase I human clinical trials.

6 Clinical Testing of New Vaccines

6.1 Single or Combined Vaccine Strategies in Human Clinical Trials

The live-attenuated CMV strain (Towne), known as *cytomegalovirus vaccine* live and currently produced by Pasteur Merieux Connaught, has undergone a number of human clinical trials over the last two decades (Table 7). Although immunogenic and safe, this vaccine has not been effective in preventing primary infection with CMV except in experimental studies using low-dose challenge with the virulent Toledo strain of CMV, unlike the efficacy of the live-attenuated varicella vaccine in preventing natural infection with VZV. The most disappointing results involved the immunization of CMV-seronegative females of childbearing age, who were not protected from naturally acquiring CMV infection from their own child. The most positive results have been in reducing the

Tab. 7 Human clinical trials of CMV and VZV[a] vaccines.

Year of report	*Vaccine*	*Experimental vaccine population*
1982	Live-attenuated CMV (Towne)	CMV-seronegative pediatric nurses of childbearing age
1984, 1988, 1991, 1994	Live-attenuated CMV (Towne)	CMV-seronegative and seropositive renal transplant candidates
1984, 1996	Live-attenuated CMV (Towne)	Healthy CMV-seronegative adults
1989	Live-attenuated CMV (Towne)	Healthy CMV-seronegative adults, subsequently challenged with low-passage isolate of CMV
1990	Nonrecombinant CMV gB protein from virus-infected cells	CMV-seronegative and seropositive adults
1998	Live-attenuated CMV (Towne)	CMV-seronegative women of childbearing age
1999	Recombinant CMV gB(-tmd) protein from CHO cells	CMV-seronegative healthy adults aged 18 to 50 years
1999, 2002	Recombinant canarypox-CMV gB virus	CMV-seronegative adults, subjected to booster immunization with CMV (Towne) or recombinant gB(-tmd) protein
2001	Recombinant canarypox-CMV pp65 virus	CMV-seronegative adults
2002	Recombinant CMV gB(-tmd) protein from CHO cells	CMV-seronegative children aged 12 to 35 months
1996,1998, 2000, 2001	Live-attenuated Oka varicella vaccine	Healthy VZV-seropositive adults aged 55 years and older
1996, 2000	Heat-inactivated Oka varicella vaccine	Healthy VZV-seropositive adults aged 55 years and older
1997, 2002	Heat-inactivated Oka varicella vaccine	VZV-seropositive bone marrow transplant candidates or recipients

[a] Does not include prelicensure trials of Oka varicella vaccine.

severity of CMV disease in seronegative recipients of organ transplants from CMV-seropositive donors.

One effort to increase the immunogenicity of the Towne vaccine has involved combining a priming immunization with replication-defective canarypox virus expressing CMV gB and subsequently boosting with the Towne strain. The MedImmune biotechnology company has been replacing parts of the Towne strain DNA genome with sequences from the low-passage Toledo strain in order to create a less-attenuated and potentially more-immunogenic vaccine. Initial human studies of these chimeric Towne–Toledo strains of CMV are under way.

A more recently developed experimental strategy for immunization against CMV in humans is the gB subunit vaccine produced in genetically modified CHO cells by the Chiron Corporation. This recombinant gB protein [gB(-tmd) in Fig. 3] is administered by intramuscular injection along with an oil–water emulsion of squalene as adjuvant, and has proved to be both safe and immunogenic after two or three doses in a number of small-scale trials in seronegative adults and children (Table 7). A human clinical trial using prior or simultaneous immunization with the live-recombinant canarypox-CMV gB virus did not improve the immune response to the Chiron gB subunit vaccine. It has not yet been demonstrated whether the induced levels of gB-specific neutralizing antibody will be protective against primary infection with CMV. The limited effectiveness of similar recombinant glycoprotein subunit vaccines in preventing sexual transmission and infection by HSV-2 glycoproteins has tempered the hope and excitement for this vaccine strategy against CMV and other human herpesviruses.

Recent human clinical trials of varicella vaccines have focused upon the use of the live-attenuated Oka varicella vaccine and heat-inactivated Oka vaccine to prevent or reduce the severity of herpes zoster/shingles in elderly seropositive adults who are at risk of VZV reactivation after decades of latency (Tables 1 and 7). These vaccines appear to be effective in boosting VZV-specific immunity without significant risk in healthy adults aged 55 years and older. Ongoing large-scale human trials should indicate whether this boost in immunity translates into long-term protection against zoster and postherpetic neuralgia.

The inactivated varicella vaccine, which carries no risk in immunodeficient recipients, has also been tested in recipients of bone marrow transplants, because these individuals are at especially high risk of serious VZV reactivation and disease. Immunization prior to the transplant and in the three months following the transplant has been shown to dramatically decrease the incidence of zoster, so that use of inactivated varicella vaccine may soon be a standard procedure in this special patient population.

6.2 Animal Models Including Animal Homologues of Human CMV and VZV

There is no nonhuman animal host for human CMV replication and disease; so animals that are experimentally immunized with CMV protein subunit or live-recombinant vaccines cannot be directly challenged with human CMV to determine whether antibody and/or cytotoxic T-cell responses are protective. There are homologous cytomegaloviruses in mice (MCMV) and guinea pigs (GPCMV), and infections of the corresponding hosts

with these two animal herpesviruses result in diseases with some similarity to human CMV disease. The GPCMV-guinea pig system is probably a better biological and clinical model system than the MCMV-mouse system because transplacental transmission and congenital disease has been demonstrated for GPCMV.

Experimental GPCMV vaccine strategies have included subunit vaccines composed of purified viral envelope glycoproteins, live-vaccines using tissue-culture passaged and attenuated GPCMV, and DNA vaccines encoding GPCMV gB or pp65. The purified glycoprotein and live-attenuated vaccines provided significant immunity to female guinea pigs immunized prior to pregnancy, and reduced the incidence and severity of congenital GPCMV in pregnant animals challenged with virulent GPCMV. Several vaccine strategies with MCMV vaccines have also been successful in protecting mice from challenge with lethal or sublethal doses of virulent MCMV. These vaccines include live-attenuated MCMV, DNA vaccines encoding the MCMV homologues of pp65 and IE1, and recombinant vaccinia virus encoding a chimeric protein with a key IE1 peptide recognized by cytotoxic T cells.

A model system with guinea pigs has been developed with a guinea pig–adapted strain of human VZV and can therefore be used for VZV-challenge following immunization with protein subunit, live-recombinant, or plasmid DNA vaccines. For example, a live-recombinant vaccinia virus expressing the gene for the IE62 tegument protein of VZV or a recombinant baculovirus-derived gE protein was able to protect guinea pigs against challenges with the guinea pig–adapted strain of VZV. There is a human VZV-like virus in monkeys, simian varicella virus, but this model system has not been extensively developed or utilized in varicella vaccine studies.

6.3 Quantitation of Immune Responses in Immunized Animals and Humans

The ideal assay for quantitation of protective immune responses following immunization with human CMV or VZV vaccines is the challenge of immunized animals or humans with a defined amount of infectious natural virus, with determination of whether infection and disease is reduced in vaccinated individuals. Experimental challenges of humans with CMV or VZV are usually not allowed for ethical reasons, so that experimental challenge with virulent human virus following immunization is possible only with the guinea pig model with human VZV. Thus, most of the quantitation of immune responses to protein subunit, live-recombinant, and DNA vaccines for CMV and VZV has utilized indirect assays for protective immune responses: quantitation of neutralizing antibody and quantitation of helper/cytotoxic T-cell responses.

Neutralizing antibody titers are more reliable than titers of antigen binding from simple enzyme-linked immunosorbent assays (ELISAs). Neutralizing antibody assays are performed by mixing serial dilutions of serum from immunized animals and control, unimmunized animals with a defined amount of infectious CMV or VZV and then inoculating human fibroblast cells in culture and quantitating a reduction in viral plaques, viral antigen production, or viral cytopathic effects. Neutralizing antibody from human clinical trials with CMV or VZV vaccines can be quantitated in the same cell culture assays as those used for antibody from experimental animals. These virus neutralization

assays are usually performed in the presence and absence of complement because many antibodies to CMV and VZV glycoproteins require complement for neutralization activity. This complement-dependent neutralization is characteristic of some herpesviruses but uncharacteristic of neutralizing antibodies for most other lipid-enveloped human viruses, such as measles, influenza, and rabies viruses.

Specific helper T-cell responses are usually determined by removing peripheral blood mononuclear cells from immunized humans or spleen cells from immunized animals, and quantitating cell proliferation following incubation in the presence or absence of specific viral antigen, typically recombinant viral protein. Quantitation of cytotoxic T-cell responses to CMV or VZV antigens in the immunized animals or humans requires antigen-presenting cells from the same host or genetically identical host that are synthesizing CMV or VZV proteins. Recombinant vaccinia viruses expressing specific *CMV* or *VZV* genes are useful for creating these target cells in cell culture because of the wide host range of vaccinia virus for different species and tissue types.

Protective immune responses in humans following immunization with new vaccines for CMV or VZV can also be quantitated in short-term studies of select high-risk populations, such as seronegative candidates or recipients of organ transplants or bone marrow transplants, or in long-term studies of seronegative but immunocompetent individuals, by following the natural incidence of virus infection and disease in the immunized population versus a corresponding nonimmunized population. Conclusive evidence of long-term immunological protection and safety is necessary before a human CMV vaccine can be licensed for general use or a new human VZV vaccine is licensed to replace or supplement the current live-attenuated varicella vaccine.

7 Concluding Remarks

As use of the licensed Oka varicella vaccine in normal childhood immunization increases to high levels, the number of cases of varicella in children and susceptible adults should decrease significantly and almost all cases of serious complications of varicella can be eliminated. The incidence and severity of zoster due to reactivation of the Oka strain of VZV in future decades may be significantly lower than that with wild-type VZV, especially if a booster immunization dose is recommended in the future. For the hundreds of millions of VZV-seropostive adults who had varicella as children prior to the availability of this vaccine, therapeutic immunization with live or inactivated Oka varicella vaccines or other vaccines that stimulate cytotoxic T-cell responses to VZV has the potential for reducing or eliminating zoster and the accompanying postherpetic neuralgia.

The future benefits of CMV vaccines are less certain in regard to congenital CMV and CMV-related disease in immunocompromised adults. Induction of protective immune responses in CMV-seronegative humans, especially in females prior to reaching the age of childbearing, may require a combination of several modern vaccine strategies unless a less-attenuated and more-immunogenic live-attenuated CMV strain is successful in clinical trials. Current vaccine strategies are beneficial in preventing severe CMV disease in the limited population of CMV-seronegative candidates for transplantation even if immunization does not prevent primary infection.

Keywords

Degradation
Breakdown of covalent bonds supporting the polynucleotide chains, caused by shearing action, low pHs, and high temperatures. The process is generally irreversible.

Stacking Forces
The forces between stacked base pairs in DNA and bases in RNA.

Melting Curve
The variation with temperature of any property, for example, absorption at 260 nm, sensitive to the native structure of DNA and RNA.

T_M
The melting temperature of DNA or RNA, determined from the midpoint of the change in the dependent variable of the melting curve, for example, absorption at 260 nm, with temperature.

Helix–Coil Transition
The point of conversion of a double-stranded helical DNA to a disordered single-stranded DNA, sometimes described (inappropriately) as random coils.

Denatured DNA and RNA are disordered nonnative states brought about by any of the many means of disturbing noncovalent bonds supporting their native conformations: heat, nonaqueous denaturing solvents, low or high pHs, low ionic strengths. The denaturation process is generally reversible.

1 Denaturation

Denaturation studies and, in particular, melting curves have many uses. They have been important for establishing conditions for the formation of DNA *heteroduplexes* and defining levels of *stringency*, denaturation mapping by electron microscopy, amplification of DNA by the *polymerase chain reaction* (PCR), determining DNA sequence variances of homologous segments and tandem and interspersed repetitive elements, profiling genomic DNA populations and estimating the relative amounts and sequence complexities of satellite repetitive elements, and determination of population and evolutionary relationships. They have been particularly important for confirming aspects of structure and sources of stability as well as for determining thermodynamic quantities associated with those sources, where temperature is an important variable.

The familiar dictum for the relationship of structure and function is especially appropriate to DNA. The strands of DNA form double helical threads of inconceivable great lengths, well suited to their role as repositories of enormous amounts of genetic information in the lineal sequences of nucleotide residues. The structures of ribosomal, transfer, and messenger RNAs, on the other hand, are strikingly different from DNA, consisting of single strands that fold into a variety of compact structural elements with shapes that enable them to serve as agents of recognition by proteins and antibiotics, gene expression, gene transport, transcription attenuation, translation regulatory agents, templates, and catalysts.

Protein and enzyme-induced alterations of the conformations of DNAs and RNAs are natural processes that, however, are not taken into account in definitions of native and denatured states. It is the practice to define the ''native'' conformations of these molecules as those existing in isolation and under physiological conditions. These molecules can be *denatured* by shifting the order–disorder equilibrium away from that favoring the native conformation by increasing the temperature or, less commonly, by the addition of denaturing solvents. Denaturation is usually a reversible process, so that if physiological conditions are restored, the native structures and biological function are restored. However, if covalent bonds are broken, the molecule is *degraded*. Unlike denaturation, degradation is usually irreversible.

1.1 Denaturation of DNA

Base–base hydrogen bonds maintain the alignment of the chains, but stacking forces appear to be the major source of support. Both are sensitive to conditions and, in particular, to temperature. Stacking forces are responsible for local variations in stability, but hydrogen bonds between bases are responsible for the high level of *cooperativity* within the molecule, resulting in an abrupt approach to the equilibrium boundary between native and denatured states, the helix–coil boundary. The high level of cooperativity reflects an unusually strong dependence of the structural state of each pair on the structural state of its neighbors, an effect that sometimes involves many hundreds of base pairs. In addition to stacking and hydrogen bonds, DNA may derive some small support from solvation effects and the occasional water bridge. On the debit side, entropic effects from restraints placed on rotation about torsional bonds and ionic forces counteract the stabilizing forces

of stacking and hydrogen bonds. Every phosphodiester group (·····O-P[O_2^-]-O·····) that links each nucleotide residue has a negative charge that creates strong repulsive forces that weaken the helix. Besides high temperatures, solvents that lessen the forces of support or promote the destabilizing forces act to shift the helix–coil equilibrium.

With exception for temperature or salt extreme organisms, conditions in cells are within the normal range of stability of DNA. The molecule undoubtedly experiences small conformational palpitations from normal mode thermal motions, but remains native because of a favorable free energy and the *cooperative* nature of the secondary interactions. Thermal motions rarely force covalently joined atoms very far from their equilibrium positions; however, occasionally they are sufficiently turbulent to cause some transient dissociation of noncovalent bonds and base pairs, resulting in a local ''breathing'' action by the two strands. Under physiological conditions, the probability that a base pair will breathe at any instant in time is only 10^{-5} to 10^{-6}, or one transient opening every 200 000 base pairs. Breathing is a random process, perhaps occurring with slightly greater probability at regions of lower stability, possibly making these regions more accessible to mutagens and therefore as ''hot spots'' of mutation.

The amount of breathing action increases with increasing temperature, gradually weakening the helix. Nevertheless, cooperative support from neighboring residues acts to restore the helix, so the structure remains essentially native almost up to the melting temperature. If the system is returned to low temperatures, the helix is seen to be unaltered. If, however, the temperature is increased further, thermal motions become more turbulent, lifetimes of pairs decrease, and eventually large numbers of pairs begin breathing in concert. At the melting temperature, T_M, (Fig. 1) where the free energy approaches zero and the equilibrium constant for the helix–coil transition approaches unity, the polynucleotide chains begin to separate, leading to nonhelical single-stranded structures. The abrupt approach to the transition caused by the cooperativity of interactions is seen in the unusual sharpness of thermally induced denaturation or ''melting'' curves. If all noncovalent bonds are broken, the chains assume the conformation of *random coils*. However, denaturation is rarely, if ever, that complete; rather, the single-stranded DNA assumes a complex disordered state with many regions of (1) single-strand stacking; (2) double-stranded hairpins; and (3) a few segments in which the structure may be random and dynamic.

2 Analytical Methods for Following the Denaturation Process

2.1 Changes in Absorbance with Temperature

Perhaps the most popular method for monitoring the denaturation process is by *electronic absorption spectroscopy*. Intense absorption bands with large extinction coefficients in the ultraviolet region are due to allowed *electronic transition moments* for the bases near 260 nm. The molar absorption coefficient for the helix, $e_{260\ nm}(P)$, is $\sim 7(\pm 0.2) \times 10^3$ L (mol × cm)$^{-1}$, more than 40% *hypochromic* to the constituent nucleotides. During denaturation, hydrogen bonds joining base pairs are broken allowing the bases to unstack, leading to an increase in the

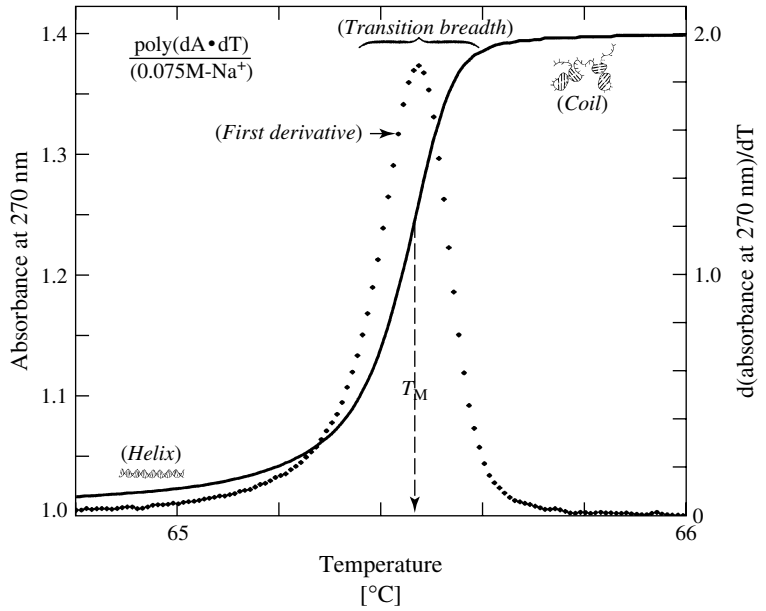

Fig. 1 Thermal denaturation (melting curve) obtained by the variation in absorption at 270 nm with increasing temperature of poly(dA·dT), a synthetic double helical DNA in a buffer consisting of 0.075 M Na^+. The bell-shaped curve of points represents the first derivative, dA_λ/dT. The T_M is usually defined as the temperature corresponding to half the hyperchromic effect. Alternately, it is the peak temperature of the first derivative curve. The free energy approaches zero at the melting temperature, T_M, where the equilibrium constant for the helix–coil transition approaches unity.

molar absorption coefficient to $\sim 10^4$ L $(\text{mol} \times \text{cm})^{-1}$. This value is close to but still less than the value for the constituent nucleotides, since some small amount of residual stacking of the unpaired bases persists beyond the denaturation temperature of the helix. The percent hypochromicity, h (%) at 260 nm, is sometimes given by

$$h_\lambda(\%) = [1 - (\varepsilon_{\text{native},\lambda}/\varepsilon_{\text{denatured},\lambda})] \times 100 \quad (1)$$

where $\varepsilon_{\text{denatured},\lambda}$ is the molar absorption above T_M. As noted by the left-hand scale of Fig. 1, the observed increase in hyperchromicity for the melting of poly(dA·dT), a synthetic double helical DNA, is ~40%. With such large changes, denaturation can be monitored with considerable precision on nucleotide residue concentrations in the micromolar range and, if the precision of data is adequate, denaturation can be represented in the first derivative, dA_λ/dT, which is better for resolving subtransitions.

DNAs of minimal sequence complexity such as poly(dA·dT) (Fig. 1) exhibit the sharpest melting curves. The melting temperature, T_M, determined from the midpoint of the transition or from the peak of the first derivative curve, can be taken as a measure of the thermal stability of the DNA. The transition breadth is an indication of the sequence complexity and

variation in the fractional (G + C) content, denoted by $F_{(G+C)}$, since the properties of (G·C) are identical to those of (C·G) and $F_{(G+C)} = 1 - F_{(A+T)}$.

A further advantage of absorption spectroscopy is that the characteristics of the base composition of natural DNAs of quasi-random sequence can be determined at different temperatures by spectral decomposition. The dissociation of (A·T) base pairs contributes more than 4x more to the absorption change at 260 nm than (G·C) pairs, while almost the reverse is true at 282 nm. Both pairs contribute equally at 270 nm; therefore, this is the preferred wavelength for expressing the ordinate of melting curves as the fraction of base pairs that have denatured.

2.2 Other Methods

Methods for monitoring the denaturation of DNA can be classified as (1) short-range physical; (2) long-range physical; (3) chemical; and (4) biological methods. A partial list of the physical methods that have been used is given in Table 1. Chemical methods include those that probe differences in the reactivity of the bases in the helical and nonhelical states, while biological methods include techniques

Tab. 1 Selected physical methods for using or following denaturation.

Methods that depend on short-range physical properties:

1. *Absorption spectroscopy*.
   Thomas, R. (1954) *Biochim. Biophys. Acta* **14**, 231; Doty, P. and Rice, S.A. (1955) *Biochim. Biophys. Acta* **16**, 446–448; (Some of the first DNA denaturation curves were carried out by taking advantage of the large hyperchromic effect associated with the destacking of base pairs).
2. *Circular dichroism*.
   Gray, D.M., Ratliff, R.L., & Vaughan, M.R. (1992) *Meth. Enzymol.* **211a**, 389. (CD measures the difference in molar extinction of the left and right circularly polarized components of monochromatic light in the region of 200 to 290 nm. As such, it is used to detect the spatial asymmetry and helical handedness as the chromophoric base pairs twist one way or the other around the major axis).
3. *Infrared spectroscopy*.

such as S1 nuclease sensitivity, reaction with antibodies, and transformation methods.

3 Factors Affecting the Stability of DNA

A number of factors from within and without the DNA affect its sensitivity to denaturation: (1) (G + C) content; (2) distribution of nearest neighbors in the DNA; (3) sequence complexity; (4) local sequence and conformational states of neighboring domains; (5) presence of wobble or other mispairs; (6) DNA length; (7) supercoiling; (8) pH; (9) temperature; (10) counterion concentration and type; and (11) various salts and nonaqueous solvents. The use of temperature for denaturing DNA is particularly convenient, figuring prominently in most studies of denaturation. Melting temperatures depend on the *intrinsic* characteristics of base composition ($F_{(G+C)}$), sequence, and chain length of the DNA specimen. Studies of the dependence of T_M on various *extrinsic* factors have been useful in the evaluation of energetics. Assuming that the fraction, f, of base pairs in the ordered (helix, h) and disordered (coil, c) states are equal at T_M, midway through the transition, $(f^c/f^h) = (f^c/[1 - f^c]) = 1$, where the free energy is given by

$$\Delta G_M = -RT \ln(f^c/f^h) = 0$$
$$= \Delta H_M - T_M \Delta S_M \qquad (2)$$

Since $T_M = \Delta H_M/\Delta S_M$, the absolute magnitudes of enthalpic and entropic contributions to stability cannot be determined from T_M alone.

3.1 Intrinsic Factors

3.1.1 (G + C) Content

T_M exhibits a linear dependence on the fraction of (G·C) base pairs, $F_{(G+C)}$. At physiological monovalent

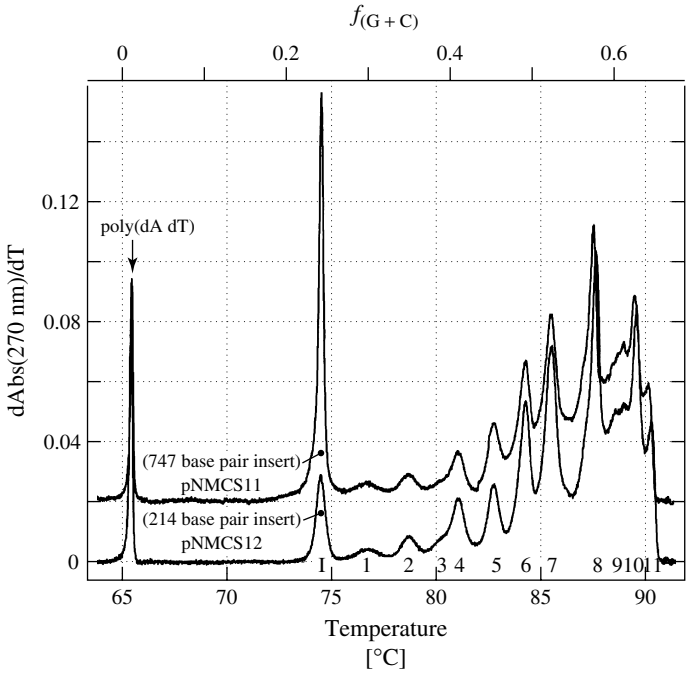

Fig. 2 The normalized first derivative of the change in absorption at 270 nm with temperature, $dA_{270\ nm}/dT$, of linearized plasmid DNAs pNMCS11 (5166 bp) and pNMCS12 (4633 bp), in which a small amount of poly(dA·dT) was added as marker. At this wavelength, the change in absorption for dissociation of (A·T) base pairs is equal to the change for (G·C) pairs, so that denaturation curves reflect changes in numbers of base pairs with temperature. With exception for the lengths of the inserts that produce the prominent subtransitions at 74.46 °C, pNMCS11 and pNMCS12 are circular plasmids with identical sequences, grown on *Escherichia coli*, isolated and linearized by enzymatic bilateral scission at the same site immediately adjacent to the insert. The insert consists of the repetitive sequence, $[AAGTTGAACAAAT]_N AAGTTGAA$, [23% (G + C)], where $N = 57$ (747 bp) in pNMCS11 and 16 (214 bp) in pNMCS12. The insert divides two very (G + C)-rich regions that serve as strong helical boundaries for the insert. Since the cut was made next to the insert, it melts according to the case I mechanism in Table 2, and the t_m of the subtransitions for the insert in the two plasmids are identical. The $[Na^+] = 0.075$ M, and the rate of heating was 6.00 °C h^{-1}.

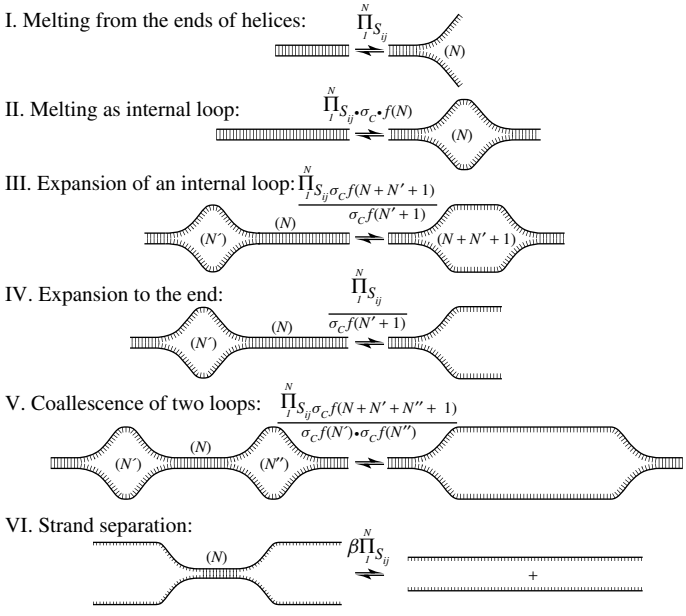
cation concentration (0.15 M-M^+), the dependence, derived from (Eq. 12) below, is given by,

$$T_M = 40.0 \cdot F_{(G+C)} + 70.04\,^\circ C \qquad (3)$$

This expression is applicable to individual DNAs or to segments of a single DNA.

As shown in Fig. 2, melting of natural DNAs occurs with denaturation of whole stretches or *domains* of base pairs. The defining characteristic of a domain is that it dissociates all at once, implying the existence of thermodynamic boundaries. In contrast with the sharp melting of DNAs of low sequence complexity, natural DNAs of quasi-random sequence melt over a range of 15 to 18 °C and exhibit the intermediate *subtransitions* summarized in Table 2. The melting curves in Fig. 2, where a small amount of poly(dA·dT) was added as marker, are for two plasmid DNAs of identical sequence over most of their 4.6 kbp length. As can be seen by the number of partially resolved subtransitions, melting takes place in intermediate steps between 74 to 91 °C, corresponding to the denaturation of sequence domains of 5 to 500 base pairs of 23 to 70% (G + C), approximated by the upper horizontal scale (Eq. 12). Domain boundaries are associated with changes in the stability and fractional (G + C) compositions since (G·C) pairs are ~20% stronger than (A·T) pairs. Sizes of domains are as small as a few pairs and sometimes larger than 500, depending on the base composition and level of *sequence complexity* of the domain and its immediate neighborhood. Complete denaturation involves the dissociation of many domains in an independent multistate fashion. Each plasmid DNA used in Fig. 2 was constructed with an insert of the same (A + T)-rich oligomeric repeat of 13 base pairs, $[AAGTTGAACAAAT]_N AAGTTG]$,

Tab. 2 Intermediate Subtransitions of DNA Helix–Coil Transitions.



but different numbers of repeats, that is, different values of N. Although the inserts in these two plasmids differ by more than 500 base pairs in length, the domain *subtransition* melting temperature t_m are identical, as is their transition breadths. There is reasonably good agreement between the *subtransition* fractional (G + C) contents $f_{(G+C)}$ of all domains determined by spectral decomposition, sequence analysis, and expression (3). The agreement is not quantitative, however, due to nearest–base pair–neighbor and neighboring-conformational effects (Table 2).

3.1.2 Distribution of Nearest Neighbors

Expression (12) is applicable to the melting of long, natural DNAs with sequences that can be expected to exhibit a random distribution of the frequencies of all 10 unique nearest-neighbor base pairs. There are $4^2 = 16$ nearest-stacked neighbors, but 10 are unique, since complementarity ensures that

$$[A-A] = [T-T],\ [A-G] = [C-T],$$

$$[A-C] = [G-T],\ [C-A] = [T-G],$$

$$[G-A] = [T-C],\ [G-G] = [C-C].$$

DNAs of biased frequencies of neighbor pairs exhibit corresponding biases in T_M. As summarized in Table 3, each neighbor pair has a different stacking energy.

Neighbor-pair biases can be readily detected in the T_M of synthetic DNAs of biased neighbor frequencies. Although both have the same $F_{(G+C)}$, the T_M for alternating co-poly[d(A – T)·d(A – T)] is almost 6° lower than for the homo-poly(dA·dT) duplex. Also, poly[d(G – A)·d(T – C)] and poly[d(G – C)·d(G – C)] melt lower by several degrees and poly[d(G – T)·d(A – C)] melt higher than predicted by the empirical Eq. (12). In instances in which the neighbor frequencies of a DNA are biased, perhaps because the specimen is short, it should be recognized that T_M depend not as directly on $F_{(G+C)}$ than they do on the mole fraction of the 10 nearest neighbors, $f_{ij}/\Sigma f_{i,j}$, where ij denotes the stack of pair i on its neighbor j, and i, j denotes the numbers of the 10 neighbor pairs in the sequence.

Tab. 3 Nearest stacked and paired neighbor energies.

	Neighbor	$dT_{ij}/d\log[Na^+]$ (°C)	(1.0 M Na^+) K	ΔH_{ij} kcal(mol-bp)$^{-1}$	ΔS_{ij} cal(° mol-bp)$^{-1}$
1	A·T/T·A	21.00	355.01	−8.00	−24.15
2	T·A/A·T	20.11	359.88	−8.31	−24.64
3	A·T/A·T	19.78	362.24	−8.45	−24.86
4	G·C/A·T	17.76	372.65	−9.13	−25.89
5	C·G/A·T	17.10	376.34	−9.36	−26.21
6	A·T/G·C	16.87	377.59	−9.44	−26.33
7	A·T/C·G	16.21	381.12	−9.67	−26.65
8	G·C/G·C	14.18	391.65	−10.34	−27.52
9	C·G/G·C	13.20	397.70	−10.72	−28.00
10	G·C/C·G	13.20	397.77	−10.72	−27.99

Values of $T_{ij}(Na^+)$ at different conditions of $[Na^+]$ are determined from $T_{ij}(Na^+) = (dT_{ij}/d\log_{10}[Na^+]) \cdot \log_{10}[Na^+] + T_{ij}(1.0M - Na^+)$, K.

3.1.3 Sequence Complexity

Equivalent but different operational definitions of sequence complexity include the total length of the nonrepetitive sequence, or the number of ways in which oligonucleotide sequence elements can be arranged, or the information content of the sequence. Sequences of lowest complexity, such as poly(dA·dT), denature over the narrowest range of temperatures (<0.1 °C), as can be seen in Figs. 1 and 2. The complexity of the repetitive insert in the plasmid of Fig. 2 is slightly greater and accordingly denatures over a slightly greater temperature range (<0.8 °C), while the plasmid DNA melts over 15 °C.

3.1.4 Conformational States of Neighboring Domains

Melting temperatures of domain subtransitions, t_m, depend on the conformational states of neighboring domains. Despite a difference of more than 500 base pairs in size, the t_m of the (A + T)-rich repetitive insert domains of the two plasmids in Fig. 2 are identical (74.5 °C) because they have the same repeat sequence and occur at the ends of the helix (case I in Table 2) where they denature independently of length and of the penultimate (G + C)-rich domain. Both *circular* plasmids were cut and linearized at a site adjacent to the inserts, positioning the insert domain at the end of the helix. However, if the plasmids are cut and linearized at a remote site that positions the insert domains internally, they melt as loops with a higher t_m (case II in Table 2). The t_m of domains that melt as internal loops depend on the size of the loop and are greater than the t_m for the same domains when melting from the end of the helix. As an internal domain, the larger insert of the plasmid pNMCS11 melts at 75.0 °C, while the smaller insert melts at 76.3 °C. A higher t_m and sharper melting for loops is due to their greater probability of renaturing and their lower conformational entropy, since the two ends of the domain are constrained by the two helical domains that border it. Since larger loops have a lower probability of renaturing than smaller loops, the Δt_m has a reciprocal dependence on loop size: smaller for large loops than for small loops, all other energetic factors being equal.

Figure 3 shows matching helix-end (case I) and helix-internal (case II) domain subtransitions for a different 200 bp (A + T)-rich repetitive domain that was installed in the same location of the same plasmid as that of Fig. 2, but now designated pNMCS22. This insert denatures at 73.08 °C when the plasmid is linearized adjacent to the domain but at 75.31 °C, more than 2 °C higher and more sharply when linearized at a remote site, forcing the domain to denature as an internal loop.

3.1.5 DNA Length and Concentration

The T_M of DNAs greater than ~3000 bp vary independently of length or concentration since the strands stay together until the last, most stable domain is denatured, allowing the two strands to diffuse away from each other, leading to a nonequilibrium situation. (This is the reason, incidentally, why the melting curve of poly(dA·dT) in Fig. 1 is slightly asymmetric, and why the final subtransitions of the melting of the plasmids in Fig. 2 are so abrupt). Short DNAs show a dependence on length and concentration because of their greater translational entropy. The effects of length on helix stability for a series of oligomers of identical neighbor-pair frequency and concentration follow a relationship of the form

$$1/T_M(N) = A + B/(N-1) \qquad (4)$$

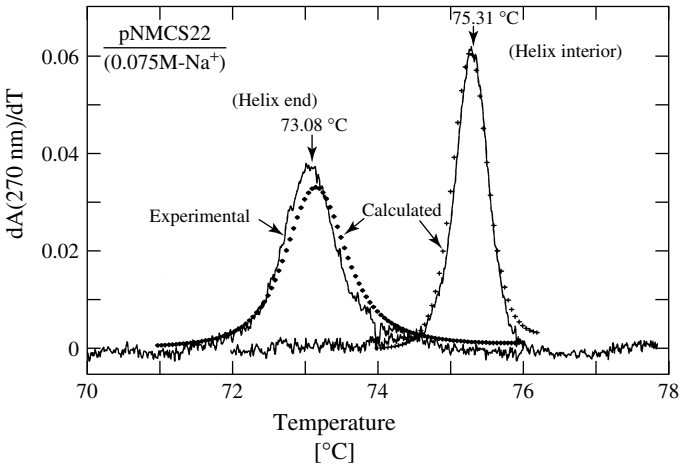


Fig. 3 Matching subtransitions for the insert sequence $[AAGTTGAACAAAAAAT]_{12}AAGTTGAA$ in pNMCS22, when melting according to the case I mechanism from helix ends ($t_m = 73.08\,^{\circ}C$) and case II mechanism from the helix interior ($t_m = 75.31\,^{\circ}C$). Except for the insert, the sequence of pNMCS22 is identical to those of pNMCS11 and pNMCS12 in Fig. 2. The continuous solid line represents experimental curves of $dA_{270\ nm}/dT$, while the curves of symbols represent the statistical–mechanical curves, $d\theta_{bp}/dT$, calculated with thermodynamic values in Table 3 and in the text. The pNMCS22 plasmid was linearized adjacent to the insert sequence for both experimental and calculated curves exhibiting the case I mechanism, while for the case II mechanism, the plasmid was linearized 800 bp away, leaving the insert in the interior of the helix with (G + C)-rich boundaries.

for oligonucleotides of length N, where A and B are constants that depend on the thermodynamic properties of the infinite polymer and on conditions. The denominator $(N-1)$ corresponds to the number of stacking interactions in an oligomer duplex of length N.

The stability of short helices also depends on oligonucleotide strand concentration, c, according to the relationship

$$1/T_M(c) = a - b \ln c \qquad (5)$$

where a and b are constants. Integration between concentrations $c_{N,1}$ and $c_{N,2}$ for oligomers of the same length N leads to

$$\frac{1}{T_{m,N}(c_{N,1})} = \frac{1}{T_{m,N}(c_{N,2})} + \frac{R}{(N-1)\cdot \Delta H_m} \cdot \ln\left[\frac{c_{N,1}}{c_{N,2}}\right] \qquad (6)$$

thus avoiding any direct consideration of the properties of the infinite polymer, whose stability is both length and concentration independent.

3.2 Extrinsic Factors

3.2.1 The Dependence of Melting Temperature on Counterion Type and Concentration

T_M exhibits a linear dependence on the logarithm of the cation concentration. Owing to the high density of negative charges, cations are attracted to DNA in large

numbers where they screen and neutralize the negative charges on phosphate oxygens O1P and O2P, reducing the effective charge on the phosphates from $-1e^-$ to about $-0.24e^-$. If the cation is a monovalent alkali metal ion M^+, where M^+ is Li^+, Na^+, K^+, ..., theory indicates that the local cation concentration close to the DNA exceeds 1 M, regardless of the bulk concentration.

The difference between the fraction of counterions condensed to native and denatured DNA, $0.76 - 0.39 = 0.37$, together with the difference in Debye–Hückel screening brought about by these counterions leads to the release of large numbers of condensed cations from the helix as DNA is converted from the high–charge density helical state to the much lower–charge density coil state, representing the physicochemical basis for the linear dependence of melting temperatures on $\log[M^+]$ as well as the strong power dependence on salt concentration of second-order *renaturation* rates, k_2 [L $(\text{mol}\cdot\text{s})^{-1}$]:

$$(\partial \log k_2 / \partial \log[Na^+]) = 3.6 \qquad (7)$$

The loss of M^+ from the helix is represented by an apparent equilibrium constant, K_M^{app}, for the reaction scheme

$$DNA^h - r^h_{M^+} \cdot M^+ \rightleftharpoons DNA^c - r^c_{M^+} \cdot M^+ + \Delta r_{M^=} \cdot M^+ \qquad (8)$$

where $\Delta r_{M^+} = (r^h_{M^+} - r^c_{M^+})$ is the number of monovalent counterions released from association with the average-size cooperatively melting domain. An increase of M^+ therefore favors the helical state while a decrease shifts the equilibrium away from the *helical* state and toward the denatured *coil* state. The amount released is relatively constant over the range $0.001 < [M^+] < 0.3$ M/L.

A limiting law has been constructed by Manning in the formalism of the *counterion condensation theory* that serves the same purpose for dilute DNA solutions as does the Debye–Hückel theory for simple electrolyte solutions. This theory, successful in explaining many of the physical properties of polyelectrolytes, is an approximation of the classical Poisson–Boltzmann theory traditionally used in numerical computations of ion–ion distribution functions and thermodynamic properties of electrolyte solutions. In the counterion condensation theory, DNA is modeled as a rigid rod with a uniform and continuous line charge, which leads to condensation by large numbers of counterions. Counterions also reduce electrostatic interactions between the fixed charges through Debye–Hückel screening, further reducing the range that would be predicted from Coloumb's law.

The key parameter leading to the spontaneous neutralization of unit charges, e, resident on the polyelectrolyte is the *linear charge density*, ξ,

$$\xi = \left(\frac{e^2}{4\pi\varepsilon_o\varepsilon_r k_B T}\right) \cdot \frac{1}{b} \qquad (9)$$

where ε_o is the permittivity constant of free space (8.8542×10^{-12} C^2 Nm^{-2}), ε_r is the dielectric constant of the aqueous solution (78.3 at 25 °C), k_B is the Boltzmann's constant (1.380662×10^{23} J K^{-1}), and b is the length of the charge separation along the mean contour axis of the polyelectrolyte. The quantity $e^2/(4\pi\varepsilon_o\varepsilon_r k_B T)$ in this expression has dimensions of length (m), the so-called *Bjerrum characteristic length*, with a value of 7.13 Å for aqueous solutions at 25 °C. Since ξ represents the ratio of the characteristic length and b, the charge density parameter is dimensionless. For B-form DNA, the mean spacing

of charges, b^{h}, is 3.34 Å/2 = 1.7 Å. Consequently, the value of ξ^{h} for native DNA is 7.14 Å/1.7 Å = 4.2 and ~1.7 for denatured DNA.

The magnitude of the charge density parameter ξ determines the extent of counterion condensation. The condensed phase of associated counterions is the consequence of thermodynamic instability when ξ exceeds $|e|^{-1}$, which is resolved by local association of counterions. If $\xi < 1$, no condensation occurs. In the case of DNA, $\xi^{h} = 4.2$, therefore counterion condensation occurs, which effectively neutralizes the fixed charges from a charge density of ξ to $|e|^{-1}$. $(\xi^{h})^{-1}$ represents the *saturated charge fraction*, which for the helix is 1/4.2 = 0.24 (0.12 for divalent counterions). The fraction of counterions that are condensed per charge is therefore given by

$$\theta^{h}_{M^+} = [1 - (\xi^{h})^{-1}] = 0.76 \qquad (10)$$

According to theory, a fraction, 0.76, of the phosphate groups of B-DNA are neutralized by a dense cloud of univalent counterions, corresponding to a local concentration of ~1.2 M-M^+. The condensed counterion phase fades rapidly with increasing radial distance from the helix. The corresponding fraction for the denatured single-strand coil state is 0.39, so the immediate concentration of counterions is only ~0.21 M surrounding denatured DNA.

Predictions of the counterion condensation theory have been confirmed in virtually every respect by experiment, including the prediction of a semilogarithmic dependence of stability on $[M^+]$. The variation of the apparent equilibrium constant, K^{app}_{M}, with melting temperature for the reaction scheme of (8) is given by the Manning-Record equation, in which electrostatic factors affecting denaturation are expressed explicitly

$$\frac{dT_M}{d\ln a^+} \approx \frac{d(T_M^{-1})}{d\ln a^+} = \frac{2RT_M^2}{\Delta H^o_M}(\Delta\theta'_{M^+}) \qquad (11)$$

where ΔH^o_M is the mean enthalpy, a^+ the *activity* (or molarity if concentrations are low) of monovalent cation, and $\Delta\theta'_{M^+}$ the fraction of condensed counterion *per mole of nucleotide residue*. Evaluation of $\Delta\theta'_{M^+}$ or ΔH^o_M is therefore possible from slopes taken from the dependence of T_M on $\ln[M^+]$. The observed salt effect, $dT_M/d\ln[M^+]$, is almost entirely entropic in origin as helices jettison large numbers of condensed counterions upon melting.

The dependence of T_M on $[Na^+]$ has been combined with the dependence of T_M on $F_{(G+C)}$ (3) into a single empirical relationship

$$T_M = 193.08 - (3.09 - F_{(G+C)}) \times (34.47 - 2.83\ln[Na^+])\ ^{\circ}C. \qquad (12)$$

which, for the same reasons explained above for expression (3), is applicable only to large DNAs of quasi-random distributions of neighbor-pair frequencies.

The dependence of T_M on monovalent counterion type follows the order $Rb^+ \approx Cs^+ > Li^+ \approx K^+ > Na^+$.

3.2.2 pH

pK_a of the four bases indicate that the range of DNA stability is limited to pHs between ~4 and 9.4. On the basis of their pK_a, in Table 4 titration curves for guanine, cytosine, and thymine frame the pH region between 4 and 9.4 as the region most hospitable to the native structure. There are practical reasons for avoiding pHs below ~5. Protonation leads to denaturation and precipitation, while still lower pHs greatly increase the rates of depurination and chain

Tab. 4 pK_a of nucleosides and nucleotides.

Nucleoside	*Site*	pK_a	pK_a *of the nucleotide 3′-phosphate*	pK_a *of the nucleotide 5′-phosphate*
Adenosine	N1	3.52	3.70	3.88
Cytidine	N3	4.17	4.43	4.54
Guanosine	N1	9.42	9.84	10.00
Uridine	N3	9.38	9.96	10.06
2′-Deoxythymidine	N3	9.93	–	10.47

cleavage. Denaturation at high pH is less problematic and represents a good method for separating the two strands from one another. Provided the strands differ in purine/pyrimidine ratio from unity, they can be separated by CsCl buoyant density gradient centrifugation at pH $\sim$ 11, where thymine and guanine residues are titrated.

3.3 Denaturing Solvents

A large number of different salts and miscible organic solvents have been investigated for their effects on the denaturation of DNA. The results are summarized in Table 5. These agents can affect the stability of DNA in two ways, by destabilizing the helix or by interacting favorably with the coil. Evidence indicates that many organic solvents interact with the bases, favoring the denatured coil state in the *helix–coil* equilibrium. Denaturing effectiveness is related to the size of the hydrophobic alkyl substituents on alcohols (*n*-butyl > *n*-propyl > ethyl > methyl), carbonates, amides, and ureas, while the addition of hydrophilic groups reduces the denaturing effectiveness of a solvent (ethyl alcohol > ethylene glycol; *n*-propyl alcohol > glycerol; cyclohexyl alcohol > inositol).

Formamide, a popular and well characterized denaturant, lowers melting temperatures by 2.4 to 2.9 °C per mole of formamide (C_F) depending on the $F_{(G+C)}$,

$$dT_M/dC_F = 0.453F_{(G+C)} - 2.88 \quad (13)$$

and the state of hydration. The inherent cooperativity of melting is unaffected by the denaturant (Fig. 4). Although dT_M/dC_F fits to a linear dependence on (G + C) content, the denaturing effect is consistent with a (G + C)-independent alteration in the apparent equilibrium constant for the *helix–coil* transition. Formamide appears to have a destabilizing effect on the helical state, where sequence-dependent variations in local hydration patterns lead to small variations in sensitivity to the denaturant. The effect is attributable to the displacement by formamide of weakly bound water in the vicinity of the helix, while the phenomenological effects of displacement are equivalent to lowering the bulk counterion concentration.

The integrity of the double helix is also sensitive to the nature of the anion of certain concentrated salts, and to a lesser extent, the cation of the salt. Salts that are most effective in shifting the *helix–coil* equilibrium are also most effective in solubilizing the bases. The following selected anions are listed in order of decreasing effectiveness in destabilizing the double

Tab. 5 Organic reagents and their concentrations (*M*) that give a 50%-level of denaturation of T_4 DNA ($F_{(G+C)} = 0.34$) at 73 °C and an ionic strength of 0.043 M.

4 Utility of Denaturation Studies

4.1 Thermodynamic Analyses

Knowledge of the forces that govern the conformation and stability of DNA is needed to understand and model the behavior of this molecule. The equilibrium concentrations of individual base pairs in all possible conformational substates must be known in order to develop plausible models for the mechanics and dynamic behavior of DNA during replication, repair, and transcription. Studies of the thermal denaturation of DNA are also important adjuncts to structural studies, providing the means for identifying various molecular sources of stability in the helix, and for quantitating the thermodynamic characteristics of those sources.

4.1.1 Simulation of Melting

Denaturation profiles of specific sequences can be simulated through the application of statistical–mechanical methods. Given suitable thermodynamic values for the various parameters, it is possible to simulate melting and predict the macroscopic properties of DNA from its sequence alone by averaging over all possible solutions for the mechanical behavior of the molecule at the molecular level. A considerable amount of both qualitative and quantitative agreement with experiment has been achieved with calculated melting curves.

During melting, six intermediate nonhelical states can be identified, represented by cases I to VI in Table 2, and distinguishable by the physical states of neighboring

domains. The simplest case is represented by melting from the ends of the helix (case I). s_{ij} is assigned as the stability constant for stacking pair i onto j at the end of a helical domain, and, in the absence of any extraordinary long-range energetic factors, by s_{ij}^N for a domain of N pairs. s_{ij} is related to temperature by

$$s_{ij} = \exp[-\Delta G_{ij}/RT] = \exp[-(\Delta H_{ij} - T \cdot \Delta S_{ij}/RT)] \quad (14)$$

where values for ΔH_{ij}^* and ΔS_{ij}^* are listed in Table 3.

In long DNAs, denaturation is primarily internal with formation of closed loops, represented by case II in Table 2. At least three factors affect the thermodynamics and temperatures at which internal domains dissociate: (1) the previously mentioned costs of unstacking each base pair in the domain; (2) the energetic costs of interrupting the helix; and (3) the energetic level of the loop:

$$K_{eq} = s_{ij}^N \sigma_c f(N) \quad (15)$$

The cooperativity parameter, σ_c, represents the weighting factor for helix interruption:

$$\sigma_c = \exp(-\Delta G_c/RT_M) \quad (16)$$

with a value of $\sim 4 \times 10^{-6}$, so that $\Delta G_c \approx 7$ kcal mol^{-1} interruptions. The statistical weight for imposing rotational and translational constraints on N denatured residues of a closed loop is a significant item in the equilibrium constant:

$$f(N) = (N+1)^{-1.7 \pm 0.2} \quad (17)$$

With these values for the various parameters, it is possible to quantitatively account for three of the six intermediate equilibria in Table 2. Cases IV to VI frequently show indications of nonequilibrium behavior owing to the abrupt increase in translational freedom, similar to that from strand dissociation. The melting behavior of domains isolated between two denatured loop regions is sometimes in nonequilibrium and is abrupt. The parameter governing strand association is given by

$$\beta = K \cdot N_\alpha \quad (18)$$

where N_α is the length of the terminal domain with α translational degrees of freedom, and K includes all factors independent of N_α, and

$$\beta = \theta_{int} - 3 \quad (19)$$

where θ_{int} represents the average fraction of intact base pairs for DNAs with at least one intact pair. β has a value of ~ 0.0015 L mol^{-1}.

A popular statistical thermodynamical model for denaturation is the canonical one-dimensional lattice with loop entropy, in which linked nucleotide residues exist in either the paired or unpaired state for each configuration of states. The free energy for the kth configuration is given by

$$\Delta G_k = -RT \ln Z_k \quad (20)$$

while the probability that the chain will assume the kth configuration is Z_k/Z. Z is the partition function over all configurations. The fraction of residues in the paired state is proportional to the statistical weights,

$$\theta_{bp} = \Sigma(N_k Z_k/Z)/N_{len} \quad (21)$$

where N_k is the number of paired residues in the kth configuration. Z_k is the product of the weighting factor in (17).

A considerable effort has been made in the evaluation of the numerous parameters in the statistical–mechanical model, and

quantitative agreement with experiment can be achieved for the melting of most domains. Calculated melting curves can be obtained with the program MELTSIM that reads in the DNA sequence and, using Poland's recursion formulae, calculates conditional probabilities at each temperature that the $(m-1)$th residue is in the paired state, given that the mth residue is paired. Following this, the unconditional probabilities that the mth residue is in the paired state are calculated. The unconditional probabilities yield $\theta_{bp}(T)$, and, thereby, $d\theta_{bp}(T)/dT$, which is proportional to normalized values of experimental $dA_{270\ nm}/dT$. A comparison of the experimental (line) and calculated (points) subtransitions for the 200 bp repetitive insert in pN/MCS22, $[AAGTTGAACAAAAAAT]_{12}AAGTTGAA$, is illustrated in Fig. 3.

4.1.2 Denaturation Maps

Denaturation maps correlate sequence position with conformational state, helix, or coil, at all temperatures, and are produced at the same time that melting curves are calculated. If the maps are accurate, they can be useful for determining the denaturation of particular base sequences and identifying specific functional regions from the sequence database. Thus, coding and noncoding sequences are readily identifiable from denaturation maps. Coding regions exhibit what has been described as a *homostabilizing propensity* with unusually large melting domains. Noncoding regions exhibit greater variability of base composition and smaller domains. Denaturation maps have also been used to demonstrate that melting temperatures and mean (G + C) base compositions of coding regions are significantly higher than those of flanking, intron, and intergenic regions, making possible the delineation of coding regions in uncharacterized DNA sequences.

4.1.3 Conditions for Equilibrium Denaturation

If quantitative significance is required of the T_M or transition breadth, experimental melting curves must be reproducible and represent true helix–coil equilibria at all temperatures. Usually, this means that curves are carried out slowly, with suitable delays at each temperature, to ensure that the property being monitored such as absorption at 260 nm is unchanging. Nonequilibrium changes are more prone to occur with decreasing ionic strengths, because the reformation of the helix during the helix–coil transition has a strong power dependence on cation concentration. As a rule of thumb, when absorbance values are monitored in continuous fashion as temperature is steadily increased, the heating rate should not exceed 10 °C per hour when the counterion concentration is in the neighborhood of 0.075 M Na^+. Rates can be faster at higher $[Na^+]$, but must be slower at lower $[Na^+]$. Below 0.02 M Na^+, the rate must be so slow that it becomes difficult to obtain equilibrium curves.

4.2 Hybridization

Denaturation is necessary for producing hybrids of complementary DNA strands from different source material, forming heteroduplexes for Southern blots or for the detection of evolutionary or mutational differences, and for joining complementary single-stranded ends for cloning DNA fragments.

4.2.1 Stringency

Studies of denaturation are required to define the level of stringency for a particular hybridization scheme. Stringency is a qualitative attribute that attempts to define the optimal conditions for hybridization between DNA strands from different sources. It refers to a set of conditions that favors the kinetic discrimination between two or more competing DNA strands during hybridization. As the temperature or solvent conditions for renaturation (hybridization) approach those for denaturation, hybrids of less perfect alignment are disfavored because of their lower stability. It is usually assumed that stringency increases as the incubation temperature T approaches the melting temperature T_M, $(T_M - T) \rightarrow 0$, so that chains of lesser sequence similarity are prevented from kinetically competing with more perfect regions of sequence and slowing up the hybridization process. As has been shown, overall, T_M are not simple measures of the stabilities of specific DNA sequences, particularly if the DNA is short. Melting curves such as those in Fig. 2 consist of innumerable intermediate states where a single T_M has no obvious significance for the hybridization of a specific domain sequence. Discrimination between two or more competing strands during renaturation is probably better achieved at room temperature at high ionic strength, which favors ready strand displacement of strands of lower similarity and stability, while at the same time avoids the hazards of thermal degradation.

4.2.2 The Potential for Degradation

Depurination of denatured strands is of significant concern when DNA is denatured by temperature. Denaturation should be conducted as rapidly as physically possible, preferably by microwave heating, in order to minimize the exposure of the single strands to the degradative conditions of high temperatures because the rate of depurination increases substantially above 50 °C and is often accompanied by spontaneous strand cleavage. Many procedures for denaturing DNA call for heating in boiling water for 2 to >10 minutes; however, the incubation time need only be long enough to ensure that thermal equilibrium has been achieved since denaturation at the high temperatures of ~100 °C is almost instantaneous.

4.3 PCR

Repeating cycles of denaturation and synthesis with the thermally stable *Taq* polymerase from *Thermus aquaticus* is the basis for the amplification of minute quantities of DNA by the PCR, a simple alternative or complement to cloning.

4.4 Sequence Variances

Measurements of levels of sequence variation within satellite elements and multicopy genes are determined from δT_M for the difference in thermal stability of homo- and heteroduplexes. Mispairs in heteroduplexes contribute to a lower overall stability, where the magnitude of δT_M is proportional to the fraction of *mispairs*. The current semiquantitative relationship finds that a 1.7% divergence in sequence yields a δT_M of 1.0 °C, however, curves of short heteroduplexes may exhibit a different dependence of δT_M for specific differences in mispaired neighbors.

4.4.1 Identification of Point Mutations and Mispair Thermodynamics

Denaturing gradient gel electrophoresis (DGGE), temperature gradient gel

electrophoresis (TGGE), and denaturing high-performance liquid chromatography (DHPLC) are sensitive methods for detecting small variations in local stability of the duplex caused by mispairs. These techniques have the capacity to detect differences in methylation of C residues in otherwise identical DNA specimens. The occurrence of point mutations implies formation of mispairs as intermediates during replication and repair of genomic DNAs. In some cases, the structures of these non-Watson–Crick mispairs require little distortion of the duplex, so their occurrence may go undetected, leading to spontaneous substitutions. TGGE has been used effectively to measure the effect of local DNA structure on mispair stacking. Recent studies have focused on the stability and structure of non-Watson–Crick mismatches, demonstrating, for example, that mispairs with 5′(C·G) and 3′(A·T) neighbors occur in the order G·T > G·A > G·G > A·G ≥ T·G > A·A = T·T > A·C > C·A, T·C, C·T > C·C. The order for other pairs and mispairs is given in Table 6.

4.5 Profiles of Genomic Base Distributions

Determinations of base distributions in total nuclear DNA are useful for what they reveal about the overall content and pattern of different sequence elements in the genome as well as what they reveal of quantitative differences between species. Melting curves of genomic DNAs yield detailed profiles of base distributions, since they reflect the mean (G + C) contents of segments only 350 ± 150 bp in length. Bacterial DNAs are ~1000 times longer than the plasmid DNAs that produced the complex melting curves in Fig. 2, and therefore they exhibit a virtual continuum of subtransitions and distributions of domain (G + C) contents. Observed melting curves of bacterial DNAs are almost Gaussian in shape with variances of only 8% (G + C), reflecting the highly streamlined genomes expected of rapidly dividing single-celled organisms.

Sequence complexities of warm-blooded vertebrates are much larger and far more cluttered and less streamlined than those of bacteria, and, accordingly, exhibit broader bell-shaped denaturation curves with sharp bands. These bands represent different amounts and types of low-complexity satellite sequence arrays that vary in (G + C) contents among even closely related species. The curves of three *artiodactyla* (class *Mammalia*), two cervids, and a bovid in Fig. 5 are typical. The profiles, adjusted in integrated areas to cellular DNA contents, are superimposable at low temperatures and fractional base contents below 40% (G + C), but exhibit a number of distinctive species-specific sharp bands at higher temperatures and (G + C) contents. Each contains at least three major satellites that have been designated I, II, and III. The 8.85 pg of nuclear DNA per diploid cell of *Alces alces* is more than 25% higher than that in other cervids due to the presence of more than three million copies of a 1-kbp satellite I, seen as a prominent band of 50% (G + C). Sequence variations are only 1 to 2% owing to a mechanism of concerted evolution involving nonreciprocal recombination.

5 Denaturation of RNA

Although the *covalent* structures of the polydeoxyribonucleate chains of DNA and polyribonucleate chains of RNA are almost

Tab. 6 Relative stabilities of Watson–Crick pairs and mispairs.

Nearest neighbor pairs		***Relative stabilities of these intervening pairs and mispairs***

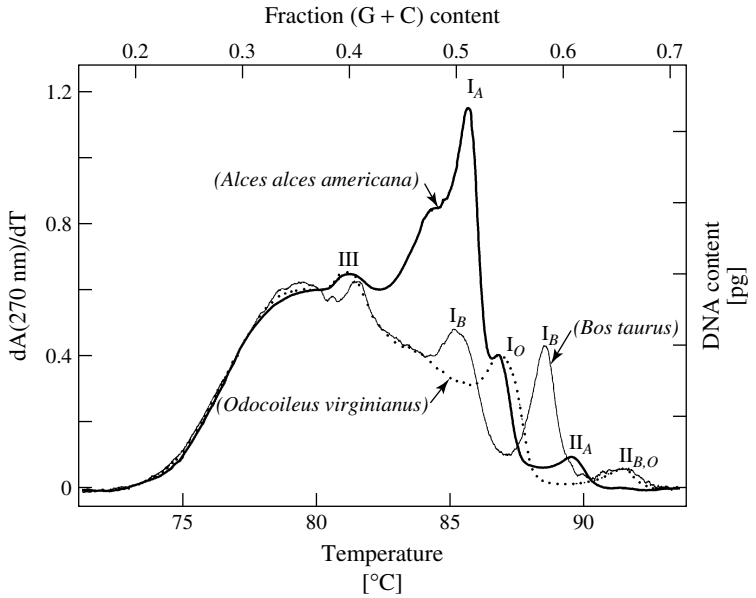

Fig. 5 Denaturation profiles of total nuclear DNA from three *artiodactyla* (class *Mammalia*), two cervids *Odocoileus virginianus* (North American white-tailed deer) and *A. alces americana* (North American moose), and a bovid, *Bos taurus* (domestic ox). The integrated area under each profile has been normalized to cellular DNA contents (pg). All three profiles exhibit bands arising from the presence of at least three major satellites that have been designated I, II, and III. The 8.85 pg of nuclear DNA per diploid cell of *A. alces* is more than 28% higher than a close cervid *O. virginianus* (6.9 pg per cell) and 18% higher than *B. taurus* (7.5 pg per cell), due to the extraordinary presence of more than three million copies of a 1-kbp satellite I, seen as a prominent band of 50% (G + C).

the same, the way these chains are synthesized, their lengths, and the way *secondary* and *tertiary* noncovalent forces act to support *native* structures are very different. In DNA, the two strands are aligned and held together over their entire lengths by Watson–Crick *hydrogen bonds* between complementary bases projecting laterally from each chain and by vertical *stacking forces* between base pairs. The shorter single-stranded chains of RNAs fold back on themselves through secondary and tertiary interactions to form *bulges, hairpin stem loops, pseudoknots, coaxial duplexes,* and *base triples*. Not surprisingly, the denaturation of these two informational biopolymers are quite different. When structures of natural RNAs of quasi-random sequence are heated, stacking and hydrogen-bonding interactions dissociate over a range of more than 70 °C, a five-fold greater range than the melting of duplex DNAs. Synthetic single-stranded homopolymeric RNAs melt over 100 °C (Fig. 6), a greater range than natural RNAs because they are completely devoid of the short hairpin structural elements responsible for cooperative behavior.

Single-strand regions of RNAs, regions in which base residues are partially stacked but unpaired, are flexible, permitting the formation of large

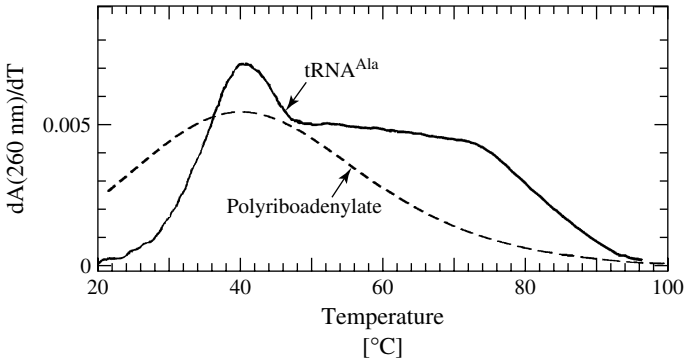

Fig. 6 Derivative melting curves of high- and low-complexity RNAs, obtained at 260 nm in 0.075 M Na^+. The solid line is the melting curve of alanine tRNA, and the broken line is the melting curve of the synthetic homopolymeric RNA polyadenylate. While melting curves of natural RNAs are normally insensitive to monovalent cation concentrations, they exhibit increasing cooperativity with increasing concentrations of some divalent cations.

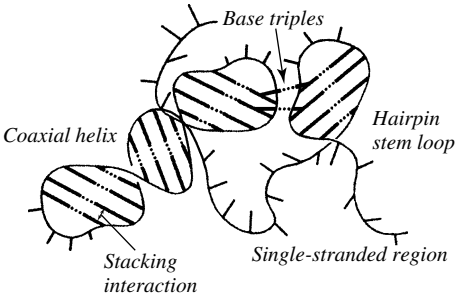

numbers of stem loops, bulges, base triples, and so on, that fold into complex shapes through interactions at the tertiary level.

The makeup of RNAs from small structural elements is apparent from the way they melt, which takes place at lower temperatures and over much wider ranges than DNA. The example of the melting of $tRNA^{Ala}$ is shown in Fig. 6. The range of melting increases with decreasing sequence complexity of the RNA as opportunities decrease for formation of hairpin stem loops. This dependence is just opposite the sharp melting of low-complexity DNA duplexes (Fig. 1).

Sharpness of melting is governed by two factors: (1) the change in enthalpy for the transition and (2) the magnitude of the equilibrium constant for creating an interruption in a linear array of stacked bases (16). The stacking enthalpy is only marginally lesser for RNAs than for DNAs; however, the interruption constant, a measure of the degree of cooperativity, is $\sim$0.5, much larger than that for DNAs, $\sim 10^{-6}$. The interruption constant corresponds to the reduction in entropy for restricting rotation about *N*-glycosidic bonds linking a base to a sugar. In single-stranded RNAs, the conformational states of stacked bases are essentially independent of the states of their neighbors, so that any detectable cooperativity during melting must reflect the denaturation of individual hairpin stem loops (Fig. 6). Thus, while the denaturation of single-stranded RNA chains is characterized by strong stacking interactions, the average length of stacked segments, given

by $1 + \sigma^{-1/2}$, is only 2 to 3 at physiological temperatures.

Keywords

Clinical Studies
Methods of testing new therapeutic strategies in patients.

Dendritic Cells
Professional antigen-presenting cells derived from bome marrow and present mainly in lymphoid tissue that are specialized for the uptake of particulate material by phagocytosis.

Immunity
The process of the induction of immune responses.

Tolerance
The process of the inhibition and/or down modulation of immune responses.

Tumor Vaccine
A vaccination agent against a special type of cancer.

Virus
An infectious agent consisting of nucleic acid enclosed in a protein coat and capable of replicating within the host cell and spreading from cell to cell.

Dendritic cells (DC) are the most potent antigen-presenting cells known today. They are the only antigen-presenting cells able to induce naïve T helper and cytotoxic T cells and are thus also known as *natures adjuvant*. In this review article, we will cover several aspects regarding the biological function of DC including antigen processing and presentation as well as antigen delivery systems including viral and non-viral systems. Specific chapters will focus on the function of DC as immunostimulators and as inductors of tolerance. A specific section will describe the interaction between DC and viruses including viral escape strategies. The final chapter will focus on the use of modified DC vaccines in the fight against cancer and virus-associated malignancies.

1 Introductory Remarks

1.1 Professional Antigen-presenting Cells

Dendritic cells (DCs), together with B cells and macrophages, belong to the family of professional antigen-presenting cells. These cells have the capacity to take up extracellular material not only for nutritional purposes but also to activate cells of the adaptive immune system such as T cells. They are able to enzymatically digest proteins into small peptides that are then presented on MHC molecules for antigen presentation to T cells. B cells process and present antigen in secondary lymphoid organs to stimulate antigen-specific T helper cells, which in turn provide feedback signals by surface ligands and cytokines. Both macrophages and DCs reside in almost all peripheral tissues as sentinel cells of the immune system to respond to an inflammatory environment or invading microorganisms. Upon immunological challenge, the functional differences between macrophages and DCs becomes apparent. Both cell types take up microbial organisms but for different purposes. Macrophages continuously ingest pathogens to inactivate them and continue their task within the

tissue until the infection is cleared. In contrast, DCs take up pathogens only once to transport them away from the site of infection to the draining lymph nodes and present them to T cells (Fig. 1).

2 DC Subsets

With respect to their hematopoietic development, several subsets of DCs have been proposed. DCs could be generated from many cell-type-restricted precursors, as shown for natural killer (NK), T, and B cells, neutrophils, monocytes, and plasmacytoid cells, but not for mast cells. Moreover, DC precursors can develop along the myeloid or lymphoid lineage and then still convert to the other respective lineage type of DCs in mice. Within secondary lymphoid organs of mice $CD4^-$ $CD8\alpha^-$, $CD4^+$ $CD8\alpha^-$, and $CD4^-$ $CD8\alpha^+$, subsets have been described. The $CD4^+$ $CD8\alpha^-$ DC are considered as ''myeloid'' DC, and the $CD4^-$ $CD8\alpha^+$ DC subset as ''lymphoid'' DC. However, typical lymphoid markers can be found on ''myeloid'' DC as well. In contrast, no markers typical for myeloid cells are found on lymphoid'' DC. Nevertheless, there are some functional differences between all of these subsets. Some of the differences might also be a consequence of the organ in which they reside at their immature stage, rather than a result of lineage-restricted commitments.

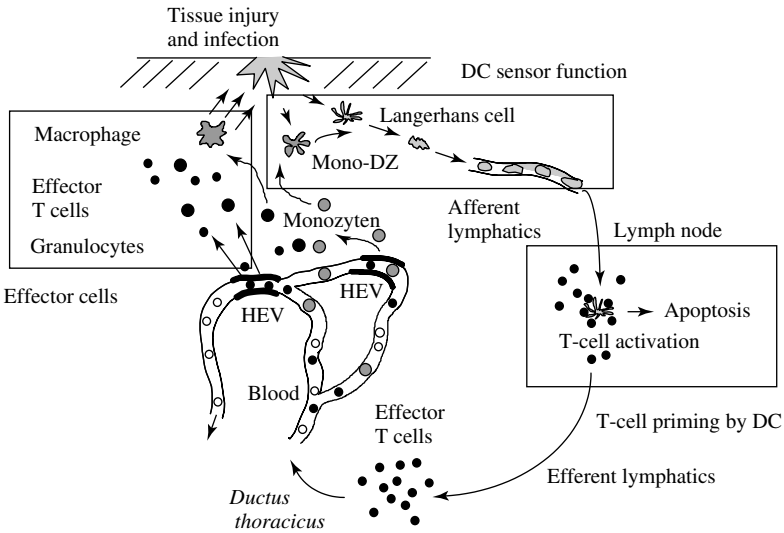

Fig. 1 Dendritic cell functions during an infection. When tissue injury allows the invasion of microbes, dendritic cells are in first line to take up the antigens, transport them into the draining lymph nodes, and present them to the T cells. Activated T cells emigrate from the lymph node and travel through the blood until they reach areas of inflamed endothelium. There the activated T cells transmigrate together with monocytes and granulocytes toward the infection. Monocytes then decide to develop into macrophages, which help to clear the infection, or into dendritic cells, which migrate to the lymph node for T-cell stimulation. This loop can be continued until the resolution of the infection.

2.1 Primary DC *In Vivo*

DCs are present in almost all organs, despite immune-privileged sites such as the central nervous system, testis, ovaries, and others, and are enriched in surface organs such as the skin and mucosa. DCs can be isolated not only from solid nonlymphoid and lymphoid organs but also from the blood or lymph.

In the skin, two DC populations can be distinguished: Langerhans cells (LCs) of the epidermis and dermal DCs. LCs are probably the best investigated primary DC type. As all hematopoietic cell types, LCs have their origins in the bone marrow where precursor cells are formed before they are released into the blood and home in onto the skin. There, the precursors remain within the dermis, divide, and subsequently migrate to the epidermis to continuously maintain the mesh of the residing LCs. LCs seem to reflect a special subset of DCs as their formation depends on the presence of transforming growth factor β-1 (TGF-β) and the transcription factor Id2, as the respective gene-deficient mice lack epidermal langerhan cells (ELC) while other DC populations are present.

In human blood, at least two major subsets of DC can be isolated: myeloid $CD11c^+$ $CD123^{dim}$ DC and plasmacytoid $CD11c^-$ $CD123^+$ DC. The myeloid DC subset is highly similar to DC that can be generated *in vitro* from blood monocytes (Sect. 2.2). The plasmacytoid DCs are a rather young population that was initially designated DC2 as it was found that after T-cell stimulation, predominantly T helper type 2 (Th2) responses resulted. More recent data showed, however, that they can also induce Th1 responses depending on a viral maturation stimulus. The major effector function of plasmacytoid DC may be to enhance antiviral immune responses by producing large amounts of interferon-α.

In human tonsils, a secondary lymphoid organ, myeloid and plasmacytoid DC can also be detected, most of which are in an immature activation state, though a few are in a mature activation state. The distribution in the mouse is very similar except that another subpopulation expressing CD8α is also present. This marker is absent in all DC populations analyzed in humans. Murine $CD8\alpha^+$ ''lymphoid'' DCs are specifically potent in cross-presenting antigens or apoptotic cells.

2.2 *In Vitro* Generation of DC from Hematopoietic Precursor Cells

The study of DCs is heavily influenced by the accessibility of tissues in the respective species studied. While all *in vivo* populations of DCs are rare, the generation of large numbers from hematopoietic precursor cells represent the most common tools that are used to study DC biology. The most accessible way to investigate the human myeloid DC is their generation from $CD14^+$ peripheral blood monocytes with granulocyte-macrophage colony-stimulating factor (GM-CSF) plus IL-4. Also, $CD34^+$ hematopoietic stem cells can be used for DC generation, but because of their lower frequency in the blood, their expansion is required before DC generation can start. Human plasmacytoid DCs were only developed from immediate blood precursors with IL-3 but do not expand. However, IL-3 is also a growth factor for myeloid DC in mouse and man. In the mouse, flt-3L seems to be the major growth factor to expand not only the plasmacytoid DC but also the myeloid DC. For the generation of murine myeloid DC, the most

effective way is to culture bone marrow precursors with GM-CSF. LCs can also be generated *in vitro* in the presence of TGF-β1.

3 Antigen Recognition and Uptake

Tissue resident DCs are in a so-called *immature differentiation state* and can be viewed as immunological sensors with high susceptibility to microbial products and the capacity to phagocytose them. At the endocytic immature state, DCs are poor presenters of antigens. Microbial challenge initiates their maturation and migration into the draining lymph node where they now have downregulated the endocytosis and upregulated the presentation of antigens transported from the peripheral organ (Sect. 4).

To differentially recognize dangerous or infectious nonself material and to ignore harmless self-antigens, DCs express specialized surface receptors. The recognition of infectious products leads to DC maturation. A wide variety of such receptors is expressed on immature DCs. Some of them initiate phagocytic mechanisms, others stimulate DC maturation and migration. However, receptor-independent mechanisms for antigen uptake have also been described.

Macropinocytosis is a receptor-independent mechanism to engulf liquid vesicles for soluble antigen capture, which is permanently active and is predominantly used by DCs and not by other professional antigen-presenting cells. Uptake of apoptotic material also seems to occur continuously in immature DCs and is mediated by a special set of receptors including $\alpha_V\beta_5$ integrin and CD36. However, both macropinocytosis and uptake of apoptotic material do not induce DC maturation, although such antigens are presented (see below).

Receptor-dependent recognition can occur *indirectly* through complement receptors (CR) binding to microbes opsonized with soluble complement factors from the serum or Fc-receptors (FcR) binding to serum antibodies.

Direct binding of antigens is mediated through so-called *antigen pattern recognition receptors* (PRRs) that recognize evolutionarily conserved pathogen-associated molecular patterns (PAMPs). One major family of such receptors has been described as the toll-like receptors (TLR). So far, 10 different TLRs have been described. They recognize different products (cell wall, DNA) of diverse types of microbes (bacteria, viruses, and parasites). The most prominent family member is TLR4, which has been identified as the endotoxin/lipopolysaccharide (LPS) receptor. TLR engagement stimulates DC maturation, which includes upregulation of MHC class I and II products, costimulatory molecules, and cytokine secretion.

For the triggering of endocytosis by DCs, other receptors are responsible. As already mentioned, the indirect mechanisms of antigen recognition by FcR and CR efficiently mediate the ingestion of the antibody- or complement-bound material. For direct recognition of antigens, some C-type lectin family members, such as the macrophage mannose receptor recognizing glycosylated structures of microbes, or the scavenger receptor family, are involved in endocytosis. When compared with fluid-phase uptake by macropinocytosis, antigens are directed to intracellular compartments that are 100 to 10 000 times more efficient when receptors are employed for

antigen uptake. Such efficient mechanisms for antigen sensing and uptake by immature DCs are a prerequisite for the excellent antigen presentation by mature DCs.

4 Antigen Processing and Presentation

4.1 Endosomal Antigen Processing for Presentation on MHC II Molecules

DCs recognize and phagocytose antigens but do not immediately process them to provide antigen presentation as observed for B cells. The antigens seem to be stored in intracellular compartments where enzymatic digestion is prevented by regulation of the pH. Proteolytic enzymes (cathepsins) are active at lower pH (<5.5) but the vesicles remain at a pH of 6.5 to 7. Storage of antigens might be useful, as the microbial products need to be transported by the DCs into the draining lymph node. This DC migration depends on the distance from the site of infection and the localization of the lymph node but takes around 8 to 24 h in mice.

Endocytosed material is located within the cytoplasm in early and late endosomes. These compartments then become enriched with cathepsins and MHC II molecules derived from the trans-Golgi-network. At this stage, MHC II molecules are protected from random peptide loading by binding to the invariant chain (Ii). For cleavage of proteins into peptides that can fit into the antigen-binding groove of MHC II molecules, acidification by proton pumps is required. This acidification of endosomal compartments might be delayed during the migration of DCs from peripheral organs to the T-cell areas of the lymph node and then released by T-cell contact. Then, sequential and highly coordinated processes of peptide editing by the cathepsins F, L, and S occur, and the replacement of MHC II-bound Ii is controlled by MHC II-like chaperone molecules HLA-DM and HLA-DO (human) or H-2DM and H-2DO (mouse). Finally, the peptide-loaded MHC II molecules are transported along microtubular structures to the cell surface, where they can now present the formerly endocytosed microbial products to $CD4^+$ T cells.

4.2 Antigen Processing and Presentation of Cytoplasmic Antigens on MHC I Molecules

Not all infectious agents can be sensed, endocytosed, and processed for loading of MHC II molecules. Viruses escape endocytosis by their fusion with the cell membrane to release their content into the cytoplasm, and intracellular immune survey takes place. Intracellular proteins can be ubiquitinylated and then enzymatically cleaved within proteasomes, which represent protease complexes. This can occur with self-proteins, tumor-derived proteins, or viral proteins. DC maturation also initiates the formation of immunoproteasomes, which employ additional combinations of proteases. The peptides released are then transported into the endoplasmic reticulum by transporters associated with antigen processing (TAP). There, the freshly synthesized MHC I molecules are still associated with other molecules that protect the MHC I groove from uncontrolled peptide loading. After the regulated opening of the groove by removal of calreticulin, tapasin associates with the MHC I/peptide complex and is transported to

the cell surface for presentation to $CD8^+$ T cells.

4.3 Cross-presentation

The term *cross-presentation* describes the phenomenon of antigen presentation across the typical rules of MHC restriction. This means that exogenous antigens that are classically endocytosed and then presented by MHC II molecules can also appear on MHC I molecules or vice versa. It has been shown that MHC I–restricted peptides within the endoplasmic reticulum can enter autophagosomes, which fuse with endosomes or lysosomes and there meet MHC II molecules for peptide loading. By far, more data are available for the reverse phenomenon, but the exact mechanism by which endosomal antigens enter the cytoplasm is still unclear.

Cross-presentation of phagocytosed apoptotic or virus-infected cells and also of endocytosed protein antigen on MHC I molecules can be observed by all subtypes of DCs *in vitro*. In mice, only the $CD8\alpha^+$ subset seems to cross-present all kinds of antigen. It is unclear whether there are functional differences between *in vitro* generated and *in vivo* generated $CD8\alpha^-$ myeloid DC, or if this is due to the antigen transport pathways and architecture of secondary lymphoid organs.

4.4 Glycolipid Antigens and Presentation on CD1 Molecules

DCs can not only present peptide fragments of proteins to $CD4^+$ and $CD8^+$ T cells but also possess a third way of stimulating other immune cells by antigen presentation on CD1 molecules. CD1 molecules show a high structural similarity to MHC I molecules but do not form hypervariable regions. They are subdivided into two groups. Group 1 CD1 genes (*CD1a, b, c*) are found in humans but not in mouse, and their expression is restricted to DCs. Only one group-2 CD1 gene (*CD1d*) is found, which is now also present in mice. *CD1d* molecules have a more broad distribution on several cell types. The antigens presented by CD1 molecules are lipid or glycolipid fragments and the cell type able to recognize these complexes are natural killer T (NKT) cells which express T-cell receptors (TCR) like T cells but also markers of NK cells. NKT cells have been described to play tolerogenic or immunogenic roles within the immune system. However, their precise tasks are unclear to date as, so far, only mycobacterial antigens have been described as natural ligands that can bind to CD1 molecules.

5 Antigen Delivery Systems

5.1 Peptide and Protein Loading

The identification of tumor-associated antigens was followed by the determination of immunodominant peptides, which are recognized on tumor cells by T cells. A broad array of tumor-specific peptides presented by different HLA class I molecules and recognized by $CD8^+$ CTLs has been identified, and, recently, several $CD4^+$ helper T-cell epitopes have been added. These defined tumor peptides can be readily synthesized in GMP quality and used to load onto *ex vivo* generated DCs. The sequence of the naturally occurring peptides can be modified by substitution of single

amino acids to improve their binding to a given HLA molecule or the affinity of the HLA-peptide complex for the T-cell receptor. Vaccination with peptide-pulsed DCs has been shown to induce both peptide-specific $CD8^+$ and $CD4^+$ T cells in healthy volunteers and even in advanced cancer patients. Although straightforward and technically easy, the peptide-based approach has some major drawbacks. First, the choice of peptides is restricted to the HLA-typing of the patient, at least for HLA class I peptides, which are less promiscuous binders than HLA class II peptides. Second, vaccination with peptide-pulsed DCs should only induce a T-cell response directed against a limited number of tumor antigens, which may not be sufficient to effectively combat the tumor. In this scenario, the tumor might escape the immune response directed against a small array of peptides and the emergence of antigen-loss tumor cell variants may occur. Third, repetitive vaccinations using relatively high peptide concentrations may favor the induction of low-affinity T cells, which are unable to recognize the tumor cells.

In addition to peptides, one could also use recombinant proteins in order to deliver defined tumor-associated antigens into DCs. This approach, however, requires good expression and purification systems and since these recombinant proteins have to be generated under GMP-conditions, they are most likely very expensive.

5.2 Apoptotic and Necrotic Cells

To optimize the antitumor effects of DC-based immunotherapy, it is tempting to allow the DCs to present the whole antigenic spectrum of a given tumor. This strategy should lead to the induction of an antitumor T-cell response directed against a broad array of tumor antigens including antigens derived from tumor-specific mutations potentially relevant for oncogenesis. Thus, the probability of tumor escape via loss of antigen should be reduced. One intriguing way is to let the DCs phagocytose whole tumor cells or their fragments, resulting in presentation and cross-presentation of tumor antigens on both MHC class I and MHC class II molecules. This would allow the simultaneous induction of tumor-specific CTLs and $CD4^+$ helper T cells, which play a critical role in antitumor immunity.

Several concerns have been raised regarding this approach. First, it is often difficult to obtain sufficient quantities of autologous tumor material from patients. The use of allogeneic tumor cell lines may present an alternative to overcome this problem and even amplify the immune response by activation of alloreactive T cells. Second, immunizing with DCs loaded with whole tumor cell preparations bears the potential risk of inducing autoimmunity, as the DCs will not only present tumor-specific antigens but also numerous self-peptides. However, it has been suggested that immature DCs induce tolerance to self-antigens derived from apoptotic cells. Thus, most patients should be tolerant to many self-peptides that DCs can present to T cells after having phagocytosed apoptotic cells. Third, a reliable monitoring of the immune response may be difficult in the latter case when compared to the use of defined tumor antigens. Fourth, T cells may be generated recognizing peptides only processed by the immunoproteasome expressed by mature DCs and not by the constitutive proteasome expressed by tumor cells. Therefore,

the tumor cells would not be recognized by these T cells unless expression of the immunoproteasome by tumor cells is induced by IFN-γ production, for example, by $CD4^+$ helper T cells at the tumor site. Finally, the optimal preparation of antigen, for example, tumor cell lysates, necrotic or apoptotic material, still has to be defined.

5.3 Antibody Mediated Uptake

Another approach yet to be looked at in clinical trials is the delivery of antigens as immune complexes to FcR-bearing DCs, which results in the formation of both MHC class II and I peptide complexes and *in vitro* can induce cytotoxic as well as helper T cells. It has been demonstrated in the mouse that immune complex delivery to DCs is particularly potent if inhibitory CD32b FcR are circumvented. Clearly, this antigen delivery method is promising as it has the potential to generate multiple epitopes for both MHC class I and II epitopes, thus lifting the restriction to HLA molecules and defined HLA-binding peptides.

5.4 Exosomes

Exosomes may be an attractive means to load DCs with antigen. These are small membrane vesicles resulting from fusion of the plasma membrane with multivesicular endosomes. They contain adhesion and costimulatory molecules, MHC products, and heat-shock proteins and are secreted by various cell types including dendritic and tumor cells. Exosomes derived from peptide-pulsed DCs induce antitumor immune responses in mice. Tumor-specific CTLs can be activated using DCs loaded with exosomes derived from tumor cells.

5.5 Genetic Manipulation of DCs

5.5.1 DNA

An alternative approach is the genetic modification of DCs. Here, one could directly transfect DCs with plasmid DNA coding for full-length tumor antigens, which then present the relevant antigens to human T cells. Plasmids can be readily constructed to not only encode a tumor antigen but also other sequences that lead to better antigen processing and T-cell stimulation. One major drawback with the transfection of DCs with plasmid-derived DNA is the fact that the transduction efficiency is relatively low. Thus, alternative strategies have to be looked into.

5.5.2 RNA

The transfection of RNA coding for defined antigens is an attractive alternative, particularly due to the development of effective electroporation protocols as a substitute for the variable transfection with naked RNA. RNA transfection also does not require costly production of GMP quality proteins and antibodies, and appears advantageous over naked DNA transfection. RNA transfection leads only to transient antigen expression that is, however, sufficient for antigen processing. RNA, in contrast to DNA, does not integrate into the genome, and therefore is much easier to work with from a regulatory point of view. RNA transfection provides an opportunity to test many defined tumor antigens (including universal ones such as survivin and telomerase). In addition, apart from defined RNA, one could also use total tumor RNA, which has the advantage, just like the approach with apoptotic and or necrotic cells, that many not-yet defined tumor antigens will be expressed and one has no restrictions regarding the patients

HLA-haplotype. However, also in this case, questions regarding autoimmunity have to be addressed.

5.5.3 Viral Vectors

The possibility of manipulating viral genomes by biotechnological techniques, together with the recent cloning of tumor-associated antigens has sparked an interest in using genetically modified viruses to express tumor-associated antigens. An increasing number of modified viral vectors have been designed for gene therapy purposes. Transduction of DCs is currently also considered a promising approach for cellular immunotherapy. This optimism has been hampered somewhat as the use of various viruses as vectors has led to the discovery of viral effects disturbing the function of DCs as antigen-presenting cells. Several virus strains that are highly interesting for the *ex vivo* transduction of human monocyte–derived DCs, that is, vaccinia virus (VV), herpes simplex virus (HSV), adenovirus (AV), influenza virus (IV), and lentivirus (LV) have been described. In addition, retroviral vector systems mediating transduction of human $CD34^+$ cell-derived DCs have also been reported.

Recently, several viral vectors have been introduced successfully in the *ex vivo* transduction of DCs, showing a very high transduction efficiency of over 90%. Since antigen concentration seems to be a crucial parameter for the induction of potent immune responses, high expression levels in DCs may represent a clear advantage.

Most of the vectors used have been adopted from the field of gene therapy, where several vector types have been designed in order to achieve the long-term expression of modified genes in nonproliferating cells. However, not all viral vectors are suitable for the *ex vivo* transduction of DCs. One of the main obstacles is the induction of cellular immune responses against viral antigens and the transgene itself, which leads to the destruction of genetically modified target cells, and the preexisting or generated neutralizing antibodies that prevent the initial or booster immunization. The aim of DC-based immunotherapy is not the long-term expression of genes in DCs but rather the induction of strong cellular and humoral immunity against an inserted tumor-associated antigens. To reach this goal, the strict avoidance of any perturbation of DC function appears critical. Furthermore, in gene-replacement therapy, one has to deal with the problem of specific cell targeting in order to induce the expression of the desired gene in a selected tissue or cell. This, however, does not represent a problem for the *ex vivo* transduction of DCs in culture.

However, when viral vectors are used to transduce DCs, the viral mechanisms of immune evasion must be taken into account. Viral escape strategies can either be designed to limit the effect of the preexisting immune response or to hamper the generation of antiviral immunity. Viruses employ various strategies to alter immune responses, including numerous mechanisms influencing the complement system and CTL and NK cell activity.

Considering the dominant role of DCs in the induction of antiviral immune responses, it is not surprising that viruses target DCs in order to block immune responses. In fact, general immunosuppressive phenomena observed, for example, during measles virus (MV) infection can be attributed to the effective interference with DC functions. Consideration of these interactions plays a role in the future development of viral vectors that potently

transduce DCs with no or only minimal inhibitory properties.

6 DC as Immunostimulators

6.1 DC Maturation

A plethora of stimuli have already been described to induce DC maturation. Most can be attributed to microbial stimuli (e.g. bacteria, viruses, parasites, or their products), proinflammatory cytokines (e.g. IL-1, IL-6, TNF-α), T-cell surface molecules (e.g. CD154), or tissue damage (cell necrosis, activated platelets, and extracellular matrix components). The diversity of signals implies that there is well-tuned coordination and combination of these signals for instructing a DC about the precise nature of the infection and the adequate immunological response required. Some of the signals are ''weaker,'' others are ''stronger'' when applied to cultured DC. Gene-chip microarray techniques have already shown that the proinflammatory cytokine TNF-α and the bacterial cell wall component LPS differentially induce a large number of genes. Inflammatory stimuli such as TNF-α have been proven weaker stimuli than microbial products. Also, exclusive CD40 signaling by the CD40-ligand on T cells does not lead to the induction of IL-12 production *in vivo*. This might indicate that an inflammation or T-cell contact to a DC must not necessarily lead to an immune response in the absence of a pathogen. Moreover, peripheral presentation of self-antigens should actively induce tolerance as not all autoreactive T cells are deleted in the thymus. Transgenic expression of TNF-α in the pancreas did cause insulitis but not autoimmunogenic diabetes.

6.2 DC Migration

In vivo, activation or maturation of the DC occurs mainly in peripheral tissues where microbial infections enter the organism. As the surface organs' skin and mucosa are highly challenged by microbes, the density of DCs in these organs is higher than in others. Upon infection or inflammation, DCs transport and process the captured antigens and transport them via the afferent lymphatics into the T-cell areas of the draining lymph nodes. DC are guided along their way by interacting with extracellular matrix components and directed by the recognition of the chemokines ELC and SLC by the CCR7 chemokine receptor.

6.3 Costimulation and Cytokines

During the process of DC maturation, the number of MHC I and II molecules on the cell surface are upregulated to improve antigen presentation. At the same time, DCs also upregulate the costimulatory molecules CD80 (B7-1) and CD86 (B7-2). Thereby, T cells receive signal 1 through the TCR and signal 2 through CD28, which is enough to trigger their proliferation and IL-2 production. At the same time, the T cells also upregulate activation markers such as CD154 (CD40L), which then ligate the CD40 molecule on the DC as a feedback signal. This can prolong the survival of the DC and improve their cytokine production. For the complete differentiation of $CD4^+$ T cells into T helper cells, additional instruction beyond the signals 1 and 2 are necessary. Polarization into Th1 cells can be provided by IL-12p70 production by DC and is triggered through TLR

ligation on DC. The signals instructing T cells to polarize toward Th2 are less clear. The Th2 driving cytokine IL-4 is not typically produced by the DC, and therefore the absence of IL-12 might be sufficient to enable a default polarization toward Th2. Similar to $CD4^+$ T cells, $CD8^+$ T cells can be primed by DCs. This feature is important for antiviral immunity and antitumor immune responses and is discussed below.

6.4 DC Interaction with B Cells and NK Cells

DC are not exclusively prime naive T-cell responses *in vivo*, but interact with other cell types of the adaptive and innate immune system. The DC has been proposed to transport intact protein antigens into the lymph nodes for B-cell recognition, and, at the same time, to present processed antigen to T cells and thereby form a triple-cell aggregate. Whether this is the rule or the exception needs further proof. Recently, it has been demonstrated that DC can directly activate marginal zone B cells in the spleen.

An interesting observation is also the signal exchange of DC with NK cells. Both cell types seem to regulate each other as NK cells can kill DCs after bone marrow transplantation and also synergize their activities by NK cell-derived IL-4 for DC and DC-mediated augmentation of NK cell killer activity against tumor cells.

7 DC and Tolerance Induction

While DC are widely accepted as stimulators of immune responses, it becomes increasingly evident that they are also major players in maintaining immune homeostasis and preventing autoimmune reactions. First of all, DCs play a decisive role in the selection of T cells in the thymus as they are more effective in presenting self-antigens than thymic epithelial cells. Thymic selection is, however, incomplete as autoimmune-reactive T-cell clones can be isolated from the circulation of healthy individuals. Therefore, additional peripheral tolerance mechanisms must exist and five have been described so far: ignorance, immune deviation, anergy, regulatory T cells, and deletion. The latter three will be mentioned here.

7.1 DC Inducing T-cell Anergy

If no DC stimulation occurs by inflammation or microbial contact, DCs remain immature, express only low amounts of MHC II, and no costimulatory molecules. Such immature DCs can also be found in secondary lymphoid tissues where naive T cells permanently pass by during their normal turnover. Antigen presentation in the absence of costimulation can lead to clonal T-cell anergy. As all isolation procedures of DC will stimulate them so that they rapidly upregulate MHC II and costimulators, active inhibition of maturation is needed to study the antigen presentation capabilities of immature DCs *in vitro*. Many treatments or protocols have been described to block maturation, and indeed, the induction of T-cell anergy or hyporesponsiveness could be shown in many cases.

Immature DCs residing in peripheral tissues would fulfil the prerequisites for T-cell anergy induction, but, under steady state conditions, there are few T cells detectable in the peripheral organs such as the skin. This situation changes when an antigenic peptide is

injected intravenously into mice; antigen-specific T cells spread over many peripheral organs. Such T cells might be anergized when arriving at a noninflammatory peripheral site upon recognizing tissue-derived self-antigen presented by immature DC.

Recently, the classical concept of T-cell anergy has been challenged because of the fact that CTLA4-deficient mice were incapable of generating T-cell anergy. Thus, the induction of T-cell anergy seems to require a negative costimulatory signal through CTLA4. This led to a new model of T-cell anergy where a low density of B7 molecules on the surface of an antigen-presenting cell leads to preferential engagement of CTLA4 and not CD28 due to its 20 to 50 times higher affinity to the B7 molecules. In this respect, it is a prerequisite that immature DC express at least some B7-1 or B7-2 molecules for the induction of T-cell anergy.

7.2 DC Inducing Regulatory T Cells

Regulatory T cells have been defined by their capacity to actively suppress functional activation of immunoreactive T cells. They are constitutively present in the circulation of healthy individuals and mice at about 3 to 10% of all T cells. This $CD4^+$ $CD25^+$ subset seems to derive directly from the thymus and regulates mainly by cell contact or a TGF-β-dependent mechanism. Another subset of regulatory T cells seems to be inducible from the naive T-cell pool. When naive T cells were repetitively restimulated in the presence of IL-10, such T cells started producing IL-10 by themselves and are therefore usually termed *$CD4^+$ IL-10^+ regulatory T cells*. For the induction of the regulatory properties of both subsets, antigen-specific activation through their TCR is required, but the effector mechanisms may partially act antigen-independent. This might especially apply for the IL-10 produced by the $CD4^+IL{-}10^+$ subset.

Regulatory T cells expand slowly after activation and this has been used to term them anergic. Anergy, however, means functional inactivation after a single suboptimal stimulation of T cells, while the induction of regulatory T cells needs repetitive stimulation in the presence of costimulation and results in functionally active T cells, although with immunosuppressive properties. Some recent data indicate that anergic T cells can be developed into regulatory T cells after repetitive stimulation.

Which DC type is able to induce regulatory T cells? For human DCs, it has been reported that immature monocyte-derived DC (Mo-DC) are able to generate regulatory T cells *in vitro*. Such Mo-DC are, however, more mature with respect to their expression of costimulatory molecules than tissue resident DCs, such as ELCs. *In vivo* experiments in mice indicate that the type of DCs inducing $CD4^+IL{-}10^+$ regulatory T cells is rather mature. The induction of $CD4^+IL{-}10^+$ cells *in vivo* might occur through steady state migratory DC, which permanently drain from peripheral tissues into the lymph nodes. These DC transport self-antigens for tolerogenic presentation. As migration, antigen processing, and presentation of tolerogenic DCs is overlapping with immunogenic DC maturation, we term such DCs *semi-mature*. The difference between tolerogenic and immunogenic mature DCs might partially result from their capacity to secrete proinflammatory cytokines, which can only be observed after microbial challenge and results in

"fully mature" DCs that prime T-cell responses.

7.3 Deletion

The complete elimination of autoreactive T cells is the decisive mechanism of T-cell selection in the thymus, but deletion of T cells can also be observed in the periphery. During the resolution of an immune response, an expanded T-cell clone with a certain antigen specificity declines in numbers by showing signs of apoptosis. When too many T cells have to compete for DC presenting the relevant antigen, the T cells might not be restimulated appropriately and might die because of neglect. This scenario also occurs when the antigen disappears after elimination of infectious microbes. In contrast, prolonged exposure to fully mature DC can lead to "activation-induced cell death" (AICD) of T cells.

The initial *in vivo* studies showing deletion of $CD8^+$ T cells as a consequence of tolerogenic cross-presentation found that bone marrow–derived antigen-presenting cells were responsible for this effect. It is now clear that $CD8\alpha^+$ DC were the responsible cell type in this experimental setting. The authors assumed that an immature stage of DC might be responsible for the cross-tolerization. Only recently, *in vitro* studies suggest that partial maturation with TNF-α and PGE_2 is required for cross-tolerance against apoptotic material with deletion of $CD8^+$ T cells as the consequence. This finding is in line with the concept that for "conventional" processing of exogenous antigen to $CD4^+$ cells, partial maturation of DC is required in the same way as for the cross-processing and cross-presenting machinery.

8 DC and Virus Interactions

8.1 HIV-1 and SIV

DC are the best antigen-presenting cells known to date and thus DCs play a crucial role in the induction of antiviral immune responses. On the other hand, many viruses are capable of developing a vast armamentarium in order to interfere with DC biology, thereby blocking antiviral immune responses. Thus, DCs often play a dual role during viral infections, influencing both pathogenesis as well as protective mechanisms.

This has also been shown in the case of HIV-1 and SIV, where HIV-1 infects selected DC populations. In addition, HIV-1 uses DCs as a vector to reach the lymphoid tissues where it infects T cells. The cell surface molecule DC-SIGN has been identified as a DC-specific HIV-1 receptor, which plays a key-role in the dissemination of HIV-1 by DCs. On the other hand, DCs are efficient antigen-presenting cells for HIV-1 and SIV antigens to both $CD4^+$ and $CD8^+$ T cells. In addition, DCs can cross-present nonreplicating viral antigens on class I MHC molecules, thereby allowing the stimulation of $CD8^+$ T cells after the uptake of antibody-coated HIV-1 and dying infected T cells.

8.2 Measles Virus

Measles virus (MV) infection is a major cause of childhood mortality in developing countries and is accompanied by a severe immunosuppression of the infected host. However, virus-specific immunity is efficiently induced, leading to viral clearance

and long-term induction of protective immunity. On the one hand, DCs play a crucial role in the induction of antiviral immune responses, while on the other hand, MV infects DCs, thereby interfering with DC biology. Inhibition of stimulated IL-12 production from MV-infected DCs might affect T-cell responses, favoring Th2 and suppressing Th1 responses. In addition, viral protein expressed on the cell surface of infected DCs most likely also inhibits T-cell responses.

8.3 Lymphocytic Choriomeningitis Virus

DCs also express the receptor (α-dystroglycan) for lymphocytic choriomeningitis virus (LCMV), Lassa fever virus (LFV), and several other arenaviruses. It has been shown that LCMV strains that bind to the receptor with high affinity replicate in the majority of DCs, causing a generalized immunosuppression, and establishing a persistent infection. This immune suppression is caused by the loss of MHC class II molecules and costimulatory molecules on the cell surface of the DCs. Furthermore, the migratory capacity of DCs is hampered by LCMV infections. It is noted, however, that LCMV strains that bind with low affinity rarely replicate in DCs and generate a potent anti-LCMV response, which is able to clear the infection.

8.4 Human Papillomaviruses

DCs also play a crucial role in the case of human papillomavirus (HPV) infection. Here, DCs (including LCs) are pivotal for the induction of T-cell dependent immunity. This, however, depends exclusively on cross-presentation of viral antigens by DCs. This exogenous pathway of MHC class I–restricted antigen presentation plays an important role in the generation of antiviral immunity against several viruses.

8.5 Herpes Simplex Virus Type 1

Herpes simplex virus type 1(HSV-1) have developed several immune escape strategies, and it is clear that many are directed against DCs. HSV-1 infected DC are defective in upregulating costimulatory molecules, do not produce cytokines, and do not acquire responsiveness to chemokines, which are required for migration to secondary lymphoid organs. Furthermore, HSV-1 downmodulates DC functions by interfering with the expression of DC-specific molecules such as CD83. In fact, CD83 is completely degraded in HSV-1 infected DCs, which coincides with a clearly reduced T-cell stimulation, representing yet another new escape strategy.

8.6 Cytomegalovirus

Cytomegalovirus (CMV) infection is characterized by host immunosuppression and multiorgan involvement. CMV-infected DCs display reduced immune stimulatory capacity.

Thus, in CMV-infected DCs, MHC molecules are downregulated, leading to a reduced antigen-presenting capacity. In addition, the apoptosis-inducing ligands CD95L (FasL) and tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) are upregulated, thereby enabling CMV-infected DCs to delete activated T lymphocytes. Interestingly, as already observed for HIV-1, DC-SIGN

serves as a receptor for CMV, thereby transmitting the virus to permissive cells. Blocking DC-SIGN by specific antibodies inhibited DC infection by primary CMV isolates, and expression of DC-SIGN or its homolog DC-SIGNR rendered susceptible cells permissive to CMV infection.

8.7 Dengue Virus

It has been demonstrated that dengue virus infects and replicates in immature human myeloid DCs. Exposure to live dengue virus led to maturation and activation of both the infected and surrounding, uninfected DCs and stimulated production of TNF-a and IFN-a. Activation of the dengue virus-infected DCs was blunted compared to the surrounding, uninfected DCs, and dengue virus infection induced low-level release of interleukin-12 p70 (IL-12 p70), a key cytokine in the development of cell-mediated immunity. It seems that DCs are the early, primary target of dengue virus in natural infection and that this infection regulates the antiviral immune response.

8.8 Ebola Virus

Ebola virus is a highly lethal pathogen responsible for several outbreaks of hemorrhagic fever. It has been shown that the primate lentiviral binding C-type lectins DC-SIGN and L-SIGN act as cofactors for cellular entry by the Ebola virus. Furthermore, DC-SIGN on the surface of DCs is able to function as a trans-receptor, binding Ebola virus-pseudotyped lentiviral particles and transmitting infection to susceptible cells. Our data underscore a role for DC-SIGN and L-SIGN in the infective process and pathogenicity of Ebola virus infection.

8.9 Epstein–Barr Virus

DCs also play a crucial role in Epstein–Barr virus (EBV) infection. There is growing evidence that DCs, and not EBV-transformed B cells, are responsible for protective antiviral immunity and that EBV nuclear antigen 1 (EBNA1) is the crucial antigen regarding resistance against all types of EBV-associated malignancies.

8.10 Influenza Virus

The exposure of human DCs to IV leads to an efficient infection *in vitro* as shown by the expression of the viral antigens HA and NS1. However, this infection does not lead to rapid cell death and only small amounts of infectious virus particles are produced. Interestingly, infected DC, but not macrophages, can induce CTL responses from purified blood $CD8^+$ cells in the absence of exogenous cytokines.

9 DC as Tumor Vaccines

9.1 Clinical Studies in Cancer Patients

The initial clinical DC-vaccination studies were performed primarily as phase I/II trials to demonstrate feasibility, immunogenicity, and lack of toxicity. Some studies revealed T-cell responses to the applied antigens and also clinical improvement even in advanced cancer patients. The heterogeneity of treated patients, vaccination schemes, DC sources, and generation

protocols as well as the lack of standardized methods to determine a successful induction of immunity makes it difficult to draw firm conclusions about the efficacy of DC-based immunotherapy. Nevertheless, many of these studies provided valuable information and a brief summary of some examples is given below.

9.2 Melanoma

The first human tumor-associated antigen was identified in melanoma and currently this is the best-studied malignancy in the context of DC-therapy. The pioneering work with peptide-loaded, mo-DCs has proven the concept of DC-vaccination to elicit tumor-specific CTL responses even in advanced cancer patients. Although these patients were heavily pretreated, clinical responses could be observed in some patients. In another clinical study, melanoma patients were vaccinated with immature, peptide- or tumor-lysate-loaded DCs. Several clinical responses were observed, but a detailed immunological readout was lacking. CD34-derived DCs have also been used in melanoma vaccination trials. Whereas in one study only moderate immune and minor clinical responses were achieved, strong immune responses as well as tumor regressions have been observed in a recent study. Recently, using mature, peptide-pulsed mo-DCs, a potent induction of tumor-specific $CD4^+$ T-cell responses could be detected in melanoma patients accompanied with a stabilization of disease in 8 out of the 16 patients evaluated. Taken together, DC-based immunotherapy in melanoma patients is particularly promising, as melanoma is an immunogeneic tumor where a multitude of tumor antigens have been described. Apart from minor side effects (fever, swelling of lymph-nodes, cutaneous reactions at the vaccination site) or the development of vitiligo in a few patients, no major toxicity was reported. Further efforts are clearly required in order to enhance the immune response, for example, by simultaneous activation of different immune cells (T cells, NK, and NKT cells).

9.3 Solid Tumors

In contrast to melanoma, many solid tumors are considered less immunogeneic and only few TAAs have been identified for these tumors. Clinical studies have been performed using DCs loaded with peptides as well as with crude tumor extracts or tumor-derived RNA.

CEA is a self-antigen overexpressed in colorectal, lung, and breast cancer. In a phase I study, on vaccinating patients with advanced CEA-expressing malignancies with peptide-pulsed cells or DCs, minor responses and stabilization of disease were observed. Other overexpressed self-antigens are Her2/neu, which is expressed in up to 30% of human breast and ovarian carcinoma, and MUC1, which is found in an aberrant form in these tumors. Patients with advanced breast or ovarian cancer were vaccinated with DCs pulsed with Her2/neu and MUC1-derived peptides after a high-dose chemotherapy. T-cell responses could be detected in 50% of patients.

Renal cancer is relatively resistant to chemotherapy; however, spontaneous remissions have been observed as well as responses to unspecific immunotherapy with IL-2. For specific immunotherapy, DCs have been pulsed with tumor lysate.

Prostate cancer is another promising candidate for DC-based immunotherapy,

since serum markers to monitor the tumor burden and defined antigens such as prostate acid phosphatase, prostate-specific antigen, and prostate-specific membrane antigen are known. Several HLA- A*0201-restricted peptides are available and have been used in a number of clinical trials with mo-DCs. Others have pulsed blood-derived DCs with a GM-CSF/PAP fusion protein and reported a significant decrease in serum PSA-levels, reflecting the reduction of tumor burden in some patients. Recently, 21 patients with metastatic prostate cancer were vaccinated with DCs pulsed with the xenoantigen mouse PAP. All patients developed T-cell responses to mouse PAP and 11 also developed responses to the human homolog. Six out of 21 patients showed a stabilization of disease. Vaccination with xenoantigens may break tolerance to self-antigens and increase the clinical efficacy of DC-based immunizations.

9.4 Virus-associated Malignancies

Targets for immune-intervention strategies in these malignancies are different viral antigens. Since they are foreign to the immune system, the challenge is rather to circumvent viral immune escape mechanisms than to induce autoimmunity. Examples for virus-associated malignancies include hepatocellular carcinoma (Hepatitis B or C virus), Burkitt's lymphoma and nasopharyngeal carcinoma (Epstein–Barr virus), squamous cell cancer of the skin, and cervical carcinoma (human papilloma virus). Studies to vaccinate against HPV-associated cervical cancer have been performed with non-DC vaccines. Some immunological effects have been reported, which, however, were only detectable after intensive *in vitro* restimulation of T cells.

9.5 Other Malignancies

Owing to the immune-privileged status of the central nervous system (CNS), it is questionable as to whether DC-based immunotherapy can be applied to patients with these tumors or not. In fact, in a recent study, patients suffering from malignant glioblastoma or astroglioma were vaccinated with immature mo-DCs pulsed with peptides eluted from autologeous tumor cells. Two patients showed $CD8^+$ infiltrates within the tumor, but no tumor regressions occurred. There is also evidence that DCs pulsed with crude tumor lysate can induce immunity and clinical responses. A study in pediatric cancer patients showed a substantial tumor regression in a child with fibrosarcoma after DC-vaccination. Tumor-specific $CD8^+$ lymphocytes and some clinical effects were also demonstrated in a recent study using tumor lysate-pulsed DCs in gynecological malignancies. However, it is difficult to monitor the successful antigen-loading and T-cell response using lysates from tumors where defined antigens have not yet been described.

9.6 Hematological Malignancies

Myeloma and B-cell lymphoma respond initially to standard chemotherapy, but are finally incurable. For both tumors, idiotypic proteins have been used as specific antigens. B-cell lymphoma was the first human malignancy to be targeted by a DC-based vaccination. Isolated blood DCs were pulsed with KLH and the patient-specific idiotype-protein (Id), which is expressed on the surface or secreted by the tumor cells. This early DC-trial with four patients showed that administration

of DCs was safe and immunogeneic with priming to the neoantigen KLH. In a subsequent study, 35 patients with B-cell lymphoma were treated with Id-pulsed DCs. T-cell and humoral anti-Id responses as well as durable tumor regressions or stabilization were reported for the majority of patients. In myeloma, idiotype- and Id-KLH-pulsed DCs were used to vaccinate patients after high-dose chemotherapy and stem-cell transplantation. Although the majority of these patients developed potent KLH responses, only minor immune responses against the tumor antigens or clinical remissions could be observed.

9.7 DC Vaccination in Infectious Diseases

The prevention of infectious diseases through vaccination represents one of medicine's greatest triumphs. However, many infectious agents such as HIV, dengue virus, *Mycobacterium tuberculosis*, *Plasmodium malariae*, and numerous others escape the immune system and standard vaccination approaches fail. The underlying immune evasion mechanisms may be attributed to a great extent to interference of the microbial pathogen with DCs and their function, for example, inhibition of DC maturation. Augmentation of the immune responses by *ex vivo* generated DCs is therefore an attractive consideration. However, DC-vaccination trials have not been performed so far. The feasibility of this approach is supported by *in vitro* studies with human cells as well as *in vivo* models in the mouse system. Induction of antiparasitic CTLs has been demonstrated *in vitro* with DCs loaded with helminthic proteins and protective immunity against bacteria has been achieved by DC-vaccination in mice. Protection against pulmonary infection with *Pseudomonas aeruginosa* following immunization with *P. aeruginosa*-pulsed DCs has also been demonstrated. One of the best-studied animal models in this regard is leishmaniasis. Lessons learned from this model may have important implications for future DC-based vaccination strategies in infectious diseases.

Peptide Bond
The amide bond formed between the α-carboxyl group and the α-amino group of two adjacent amino acid residues in a peptide.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.

ISBN: 3-527-30545-9

Peptide
The common usage for a shortened form of polypeptide. Peptide refers to any organic compound composed at least partially of amino acids linked by peptide bonds. The distinction between peptides and proteins is arbitrary with the borderline often placed at 50 to 100 amino acids.

Residue
An amino acid residue is an amino acid in a peptide linkage. Its structure is the same as that of the free amino acid except that it has lost a molecule of water consisting of a hydrogen from the α-amino group and a hydroxyl from the α-carboxyl group.

Epitope
The term *epitope* is used to operationally define that portion of a protein that interacts specifically with some component of a biological system. With respect to the immune system, an epitope was initially defined as that portion of a protein that is recognized by an antibody. However, the usage has now been expanded to include portions of proteins that interact in other ways, such as epitopes that interact with T-cell receptors to induce a heightened antibody response toward another epitope.

A peptide consists of two or more amino acids linked together by amide bonds. Synthetic peptides are peptides that have been produced with organic, synthetic techniques to either mimic naturally occurring peptides or segments of naturally occurring proteins, or to interact in a specific manner with biological systems. Synthetic peptides are important molecules for biomedical research and medicinal chemistry that are useful for understanding biological systems and that have important applications in the development of vaccines and therapeutic agents and the process of *de novo* drug discovery.

1 Overview

Synthetic peptides are organic compounds, generated by synthetic chemical techniques, which are composed of two or more amino acids linked together by a peptide bond. They are often intended to resemble or duplicate naturally occurring peptides or segments of naturally occurring proteins. Synthetic peptides can be linear (**I**), cyclic (**VII**), or branched (**VI**) (bold roman numerals refer to the structures in Fig. 1) and are usually composed of, but not limited to, the 20 naturally occurring L-amino acids or their D-amino acid counterparts (**IV**). Synthetic peptides may also contain non–amino acid constituents (**III**) as well as chemical modifications of the natural side chains (**VI**, **IX**) or the polypeptide backbone structure (**V**). Synthetic peptides are important as tools for research in the biological and biomedical sciences, and a significant number

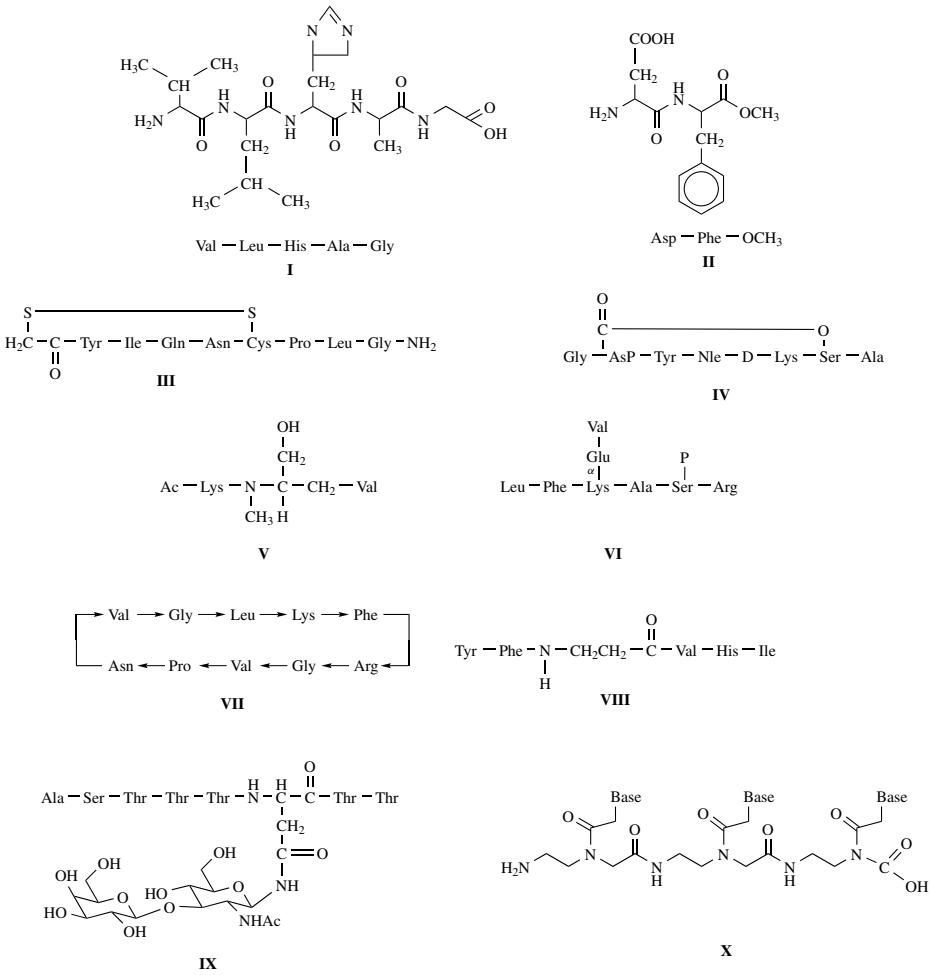

Fig. 1 Examples of synthetic peptides that demonstrate many of the features of chemistry and its nomenclature described in the text. The structures are referred to in the text by their roman numerals: **I**, a typical linear pentapeptide composed of α-peptide bonds and its three letter symbol designation; **II**, the commercial sweetener, aspartame; **III**, [β-mercaptopropionic acid[1]] oxytocin containing a terminal non–amino acid constituent and illustrating the disulfide linkage for clarity; **IV**, a heptapeptide containing a nontypical amino acid (Nle, norleucine) a D-amino acid and an intramolecular lactone bond; **V**, a tetrapeptide containing an N-terminal acetyl group, an alkylated α-amino group, and a fully reduced α-carboxyl or alkane constituent as part of the backbone structure; **VI**, a hexapeptide containing a phosphorylated serine residue and a branched chain connected by a peptide bond between the ε-amino group of lysine and the α-carboxyl group of glutamic acid; **VII**, circular depiction of a cyclized decapeptide; **VIII**, a hexapeptide containing a β-peptide bond; **IX**, an octapeptide with a glycosyl group as a sidechain modification; **X**, an example of a peptide nucleic acid (note the unusual nature of the backbone).

of synthetic peptides have pharmaceutical and commercial uses. For instance, synthetic polypeptide hormones have useful clinical applications, and the commercial sweetener aspartame, a dipeptide (N-L-α-aspartyl-L-phenylalanine-1-methyl ester, **II**), is the basis for an entire industry and is perhaps the best-known synthetic peptide.

Naturally occurring peptides have played crucial roles in life processes since the very beginnings of living organisms. Large peptides, generally referred to as proteins, serve in catalytic, structural, recognitive, and signal transduction processes in both plants and animals. Small peptides have equally important functions as hormones, growth factors, neurotransmitters, and cytokines.

The science of producing and using synthetic peptides is generally recognized as having its beginnings in the late 1800s and early 1900s and is associated mainly with the work of Theodore Curtius and Emil Fischer. Fischer, who is generally regarded as the father of peptide chemistry, was the first to introduce the concepts of peptides and polypeptides and present protocols for their synthesis. Over the years, many investigators have contributed to the advancement of the production and use of synthetic peptides. Perhaps the greatest of these was the introduction of the solid-phase method of synthesis by Bruce Merrifield in 1963. This development, along with improvements in chemistry, instrumentation, and analytical techniques by a large number of other investigators, has made it possible to obtain useful amounts of synthetic peptides on a relatively routine basis.

The genesis of a synthetic peptide can be viewed as being composed of several discrete steps ultimately culminating in its use or application. These steps consist of the design of the peptide to serve a specific purpose, its chemical synthesis, and the evaluation of the integrity of the product, which includes its purification from the initial crude product of the synthesis.

2 Design and Structure

The design of a particular synthetic peptide is often based on its intended use and on considerations of the synthetic chemistry. With modern synthetic techniques it is possible to produce peptides containing in excess of 100 amino acids, although those shorter than 50 are much more common and easier to synthesize. Short peptides tend not to exhibit preferred or stable solution conformations but rather possess a large degree of flexibility. As peptides increase in length, they have a greater tendency to adopt elements of secondary structure, such as helices and β-sheet structures connected by discrete turns, which impart an overall decrease in flexibility. These are structures generally found in naturally occurring proteins and large peptides that are responsible for their specific biological interaction. From a knowledge of the features that contribute to the formation of these structures, peptides can be specifically designed to contain them.

The physical, chemical, and physiological properties of synthetic peptides are determined by the nature of their constituent amino acids. In nature, the range of structure of these amino acids is vast. In addition to the 20 common ribosomally incorporated ''protein'' amino acids, there are enzymatically formed, posttranslational modifications to these amino acids found in proteins as well as hundreds of naturally occurring, enzymatically synthesized amino acids not found in proteins.

Add to this the imagination of a synthetic chemist, and the possibilities are almost limitless.

In its most basic sense, a synthetic peptide consists of at least two amino acids joined by a peptide bond, which is an amide bond formed between the amino group of one amino acid and the carboxyl group of an adjacent amino acid (Fig. 2). Peptides composed of more than two amino acids possess a number of these amide bonds in series known as the *peptide backbone*. This backbone structure is an important contributor to the overall peptide structure. The resonance properties of the carbon–nitrogen peptide bond give it a substantial double bond character. As a result the amide bond is flat, with the carbonyl carbon, oxygen, nitrogen, and amide hydrogen all lying in the same plane. Thus, no free rotation occurs around the carbon–nitrogen bond. The torsional angle of that bond, called ω, is defined by the atoms $C\alpha-C(O)-N-C\alpha$, and because of the double bond character and the large energy barrier to rotation (25 kcal mol^{-1}), there are two rotational isomers: trans ($\omega = 180^\circ$) and cis ($\omega = 0^\circ$). The trans-isomer possesses the lower energy and is generally found for all peptide bonds not involving proline. The energy of the trans X-Pro bond is somewhat elevated and the barrier to rotation is lowered. Thus, proline-containing peptides will often exhibit cis–trans isomerization.

In addition to ω, the peptide backbone can be completely described with two additional angles, ϕ and ψ. ϕ is the angle described by $C(O)-N-C\alpha-C(O)$ and ψ is described by $N-C\alpha-C(O)-N$. By convention, the angle ϕ is 180° when the two carbonyl carbons are trans to each other and the angle ψ is 180° when the two amide nitrogens are trans to each other.

Peptide and protein structure is organized in several levels. The order of amino acids, or amino acid sequence, is referred to as the primary structure. The secondary structure is the folding up of the primary structure into discrete elements such as helices, sheets, and turns. The tertiary structure describes how the elements of secondary structure found in a single peptide chain interact with each other to produce a final three-dimensional arrangement. The design of synthetic peptides is basically concerned with primary and secondary structure; the concern with secondary structure becoming more important as the size of the peptide increases. With the largest synthetic polypeptides,

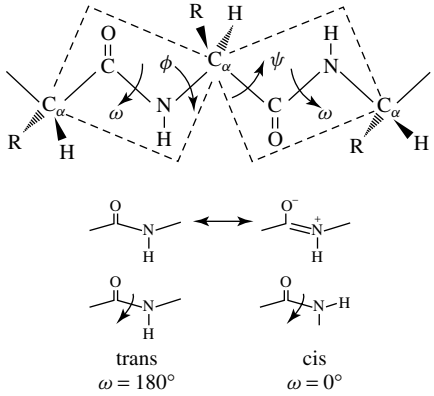

Fig. 2 A stretch of polypeptide demonstrating the planar nature of the peptide bond, the angles that describe the conformation of the polypeptide backbone, and the chirality of L-amino acids. The resonance structures of the peptide bond and cis- and trans-peptide bonds are also shown.

elements of tertiary structure may also be important.

Secondary and tertiary structures are determined by, and can be influenced by a variety of interactions. Basically, secondary and tertiary structures develop from noncovalent interactions such as hydrogen bonds, salt bridges, and hydrophobic interactions resulting from main chain and side chain atoms interacting with each other and with bulk solvent.

The synthetic approach allows the introduction of novel or unusual components such as D-amino acids (**IV**), other unnatural amino acids (**IV**, **X**), ester or alkyl backbone bonds in place of the normal amide bond (**V**), N- or C-alkyl substituents (**V**), amino acids in which the amino group is not attached to the α-carbon (**VIII**, **X**), side chain modifications (**VI**, **IX**), and constraints such as disulfide bridges (**III**) and side chain amide or ester linkages (**IV**). The results of such changes may be higher biological potency, greater stability resulting in longer biological lifetime, or the ability to specifically interact with or covalently label a biological macromolecule or receptor for localization or structure–function relationship studies.

Peptide solubility is another potentially important concern in the design of a synthetic peptide. If the intention is to work with a peptide in aqueous media, it is important that the peptide has sufficient polar character for solubility. This is a point that might especially be overlooked when a peptide is made based on a sequence found internally in a protein. The solubility properties of a particular peptide may be vastly different from the protein when it is removed from the context of the surrounding protein structure. The peptides, composed completely of uncharged amino acids, tend to be less soluble in aqueous environments and their insolubility tends to increase as the size of the peptide increases. Therefore, it is advisable to incorporate charged amino acids into a synthetic peptide when possible. Histidine, lysine, and arginine promote solubility at pHs where their side chains tend to be positively charged and aspartic acid and glutamic acid promote solubility at pHs where their side chains tend to be negatively charged. The contribution of the charge properties of the α-amino and α-carboxyl groups should also be taken into account. In borderline cases, uncharged, polar groups can also promote solubility.

3 Nomenclature

A proper use of nomenclature for describing peptides is important. The International Union of Pure and Applied Chemists (IUPAC), in conjunction with the International Union of Biochemists (IUB), have formulated a set of guidelines for peptide nomenclature (*J. Biol. Chem.* (1985) **260**, 14–42). These guidelines are too extensive to be described here in their entirety, but some of the more common conventions are presented.

The sequence of amino acids within a peptide is usually designated with either the one-letter or three-letter amino acid symbol (Table 1). The amino acid symbols denote the L-configuration unless designated with a D or DL preceding the symbol (**IV**). In the case of linear polypeptides, the convention is to express the peptide left to right from the amino-terminus to the carboxy-terminus (**I**). Thus, a pentapeptide might be represented either as V-L-H-A-G or as Val-Leu-His-Ala-Gly. The α-amino group is assumed to be at

Tab. 1 Common symbols for amino acids in expressing peptide structure.

Residue	*Three-letter symbol*	*One-letter symbol*[a]
Alanine	Ala	A
Asparagine[b]	Asn	N
Aspartic acid[b]	Asp	D
Arginine	Arg	R
Cysteine	Cys	C
Glutamic acid[b]	Glu	E
Glutamine[b]	Gln	Q
Glycine	Gly	G
Histidine	His	H
Isoleucine	Ile	I
Leucine	Leu	L
Lysine	Lys	K
Methionine	Met	M
Phenylalanine	Phe	F
Proline	Pro	P
Serine	Ser	S
Threonine	Thr	T
Tryptophan	Trp	W
Tyrosine	Tyr	Y
Valine	Val	V
Hydroxylysine	Hyl	
4-Hydroxyproline	Hyp	
α-Aminobutyric acid	Abu	
Norvaline	Nva	
Norleucine	Nle	
Homoserine	Hse	
Homocysteine	Hcy	
Ornithine	Orn	
Citrulline	Cit	
α-Aminoisobutyric acid	Aib	
γ-Carboxyglutamic acid	Gla	

[a] Symbols for less common amino acids should be defined in the individual publications in which they appear.
[b] Asx or B and Glx or Z are used when the distinction between aspartic acid/asparagine and glutamic acid/glutamine is uncertain. This convention is most commonly applied in sequence analysis.

the left-hand side of the amino acid symbol when using hyphens and at the point of the arrow when using arrows for special cases such as cyclic peptides (**VII**, and see below). Normally, when the termini are free amino or carboxyl groups, no additional designation of this is necessary. However, in order to avoid confusion or ambiguity, the state of the termini is often indicated (**III**). Free termini are designated with a H– at the amino end and an –OH at the carboxyl end so that the above peptide would be written as H-Val-Leu-His-Ala-Gly-OH. Similarly, a C-terminal amide or aldehyde group would be designated by $-NH_2$ or –H respectively.

Occasionally, the names of small peptides will be written out. In this case, the names of all amino acids contributing carboxyl groups to peptide bonds end in -yl, and the amino acid with the terminal carboxyl group retains its original name. The peptapeptide shown above and in **I** would thus be expressed as valylleucylhistidylalanylglycine.

Cyclic peptides are usually expressed on a single line of text, similar to linear peptides, with a line or "extended bond" drawn to connect the joined amino acids that lead to the cyclic nature of the peptide. If the amino acids are joined between side chains, such as in disulfide bonds or side chain lactams, the line starts and ends in the middle of the amino acid name or abbreviation, such as

Gly-Val-Glu-Ala-Leu-Ile-Lys-Ala-Thr.

If the structure drawn in this manner is ambiguous, additional atoms can be illustrated, as shown in Fig. 1 (**III**, **IV**), to clarify the meaning.

If the connection is between the α-amino and α-carboxyl groups of the termini, the line is drawn from the sides of the names, such as

Gly-Val-Glu-Ala-Leu-Ile-Lys-Ala-Thr.

In this case, the N→C direction is read left to right. If the peptide is written out in a circular fashion, as if it was written along the circumference of a circle or a loop, then the N→C direction must be designated by arrows (**VII**). Finally, cyclic peptides are sometimes designated as such with the prefix *cyclo*, such as cyclo(Gly-Val-Glu-Ala-Leu-Ile-Lys-Ala-Thr), to indicate the same structure as immediately above.

Synthetic analogs of naturally occurring peptides that have specific names associated with them represent a special case. These include substances such as insulin, oxytocin, enkephalin, vasopressin, and bradykinin to name a few. For example, the polypeptide hormone, oxytocin, has the structure

Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-Gly-NH2,

where the cysteine residues form a disulfide bridge. If one or more amino acids are replaced in the synthesis of an oxytocin analog, the new amino acids and their positions are placed in brackets before the name. Thus, [Phe^2, Asn^4]-oxytocin refers to an oxytocin analog in which the tyrosine at position 2 and the glutamine at position 4 have been replaced with phenylalanine and asparagine respectively. The prefix *endo* is used to designate the insertion of an extra amino acid into the chain. Thus, *endo*-Ala^{7a}-oxytocin denotes an alanine insertion between Pro^7 and Leu^8. Similarly, deletion of an amino acid is designated by the prefix *des*, for example, *des*-Ile^3-oxytocin denotes that Ile at position 3 has been deleted. Peptide sequences that form fragments of a longer sequence that has a trivial name are designated by the trivial name followed by numbers giving the positions of the first and last amino acids and then a designation describing the number of amino acids in the fragment. For example, the peptide Tyr-Ile-Gln is a segment of oxytocin (see above) and can be designated as oxytocin-(2–4)-tripeptide.

4 Synthesis

Peptides can be synthesized either in solution, which is the classical approach, or by solid-phase methods. With the exception of specialized applications in which solution phase chemistry is used

because it is easier, less expensive, or the necessary chemistry is not amenable to the solid-phase method, most peptides made for research purposes are synthesized with the solid-phase method that was introduced by Merrifield in 1963. This technique, for which he was awarded the Nobel Prize in Chemistry in 1984, was primarily responsible for opening the way to the widespread use of synthetic peptides in chemical and biomedical investigations.

Solid-phase methods are readily automated and most solid-phase syntheses performed today are done with the aid of machines. A variety of peptide synthesizers are commercially available for batchwise and continuous flow operations as well as for the synthesis of multiple peptides within the same run.

4.1 The Solid-phase Method

The solid-phase approach to peptide synthesis is presented in Fig. 3. Basically, it consists of anchoring the growing peptide to an insoluble support or resin. This is usually accomplished through the use of a chemical handle that links the support to the first amino acid at the carboxyl terminus of the peptide. Subsequent amino acids are then added, one at a time, in a stepwise manner until the peptide is fully constructed. The solid-phase method allows excess reagents and soluble reaction by-products to be easily removed by filtration and washing, thus doing away with the need to isolate or crystallize the product after each step.

Synthesis of the growing polypeptide chain is accomplished by formation of an amide bond between the free α-amino group of the receiving amino acid (anchored to the support) and the activated α-carboxyl group of the incoming amino acid (in solution). Note that synthesis proceeds from the carboxy end to the amino end. To prevent unwanted side reactions with reactive amino acid side chains and self-coupling of the α-carboxyl group of one incoming amino acid to the α-amino group of another incoming amino acid, these groups must be protected at the appropriate times during synthesis. As depicted in Fig. 3, the group protecting the α-amino group of the amino acid being coupled must ultimately be removed, after coupling is complete, in order to accept the next amino acid during the next cycle. Chemical groups that allow this are referred to as ''temporary protecting groups''. The reactive amino acid side chains, on the other hand, must remain permanently protected throughout the synthesis. Thus, chemical groups that accomplish this are referred to as ''permanent protecting groups''. At the end of the synthesis, the completed peptide is cleaved from the resin support and the permanent protecting groups are removed, usually in a single step process, to yield the desired peptide product.

4.2 Chemistry

A number of different chemical approaches for the synthesis of peptides on solid phase supports have been investigated and are in use today. Generally, two levels of protecting group stability are required. The permanent protecting groups must be such that they are stable during the repetitive conditions of removing the temporary protecting groups from the growing peptide chain. However, the permanent protecting groups, as well as the attachment handle holding the peptide to the support, must ultimately be removed under conditions

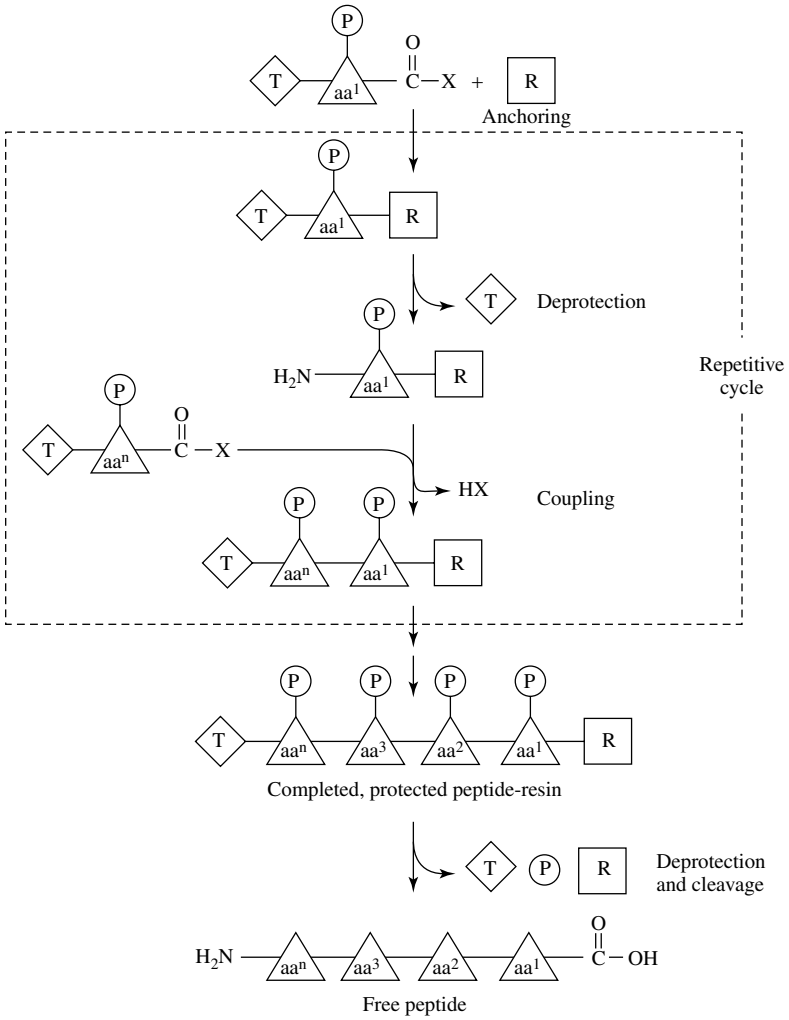

Fig. 3 Stepwise solid-phase synthesis of linear peptides. R, resin or insoluable polymeric support; T, temporary protecting group; P, permanent protecting group; X, denotes activated carboxyl group; $aa^1 \ldots aa^n$, amino acid residues numbered from the C-terminus.

Fig. 4 Common protection schemes for solid-phase peptide synthesis (a) Protection scheme for solid-phase synthesis based on the Boc group utilizing graded acidolysis. The Boc group is removed at each step by trifluoracetic acid (TFA). The permanent side chain protecting groups and the PAM linkage are cleaved simultaneously by hydrofluoric acid (HF) or other strong acid. (b) Mild orthogonal protection scheme for solid-phase synthesis based on the Fmoc group. The Fmoc group is removed at each step by the base catalyzed elimination mechanism, usually using piperidine, as shown. Permanent side chain–protecting groups and the HMP/PAB linkage are cleaved by treatment with TFA. (Figures are reprinted with permission from Freeman, W. H. and Fields, G. B., et al. in Grant, G. A. (Ed.) (2002) *Synthetic Peptides: A User's Guide*, 2nd edition, Oxford University Press, Oxford, New York).

that do not harm the underlying peptide structure. Two general methods have emerged as the most common and are depicted in Fig. 4. They are referred to as either ''Boc'', which uses the tert-butyloxycarbonyl group, or ''Fmoc'', which uses the 9-fluorenylmethyloxycarbonyl group for temporary α-amino protection. Today, the Fmoc chemistry is probably used more often than the Boc chemistry largely because the permanent protecting groups and the resin handle can be removed under milder conditions with reagents that do not present as much of a potential hazard as those used for Boc chemistry. However, the Boc chemistry remains a vital and useful chemistry that is still used by many peptide chemists.

A wide variety of permanent protecting groups are available for these two general approaches and a few of them are depicted in Fig. 4 and Table 2. The Boc strategy relies on graded acidolysis to selectively differentiate between temporary and permanent protection. Temporary protecting groups are removed by treatment with trifluoroacetic acid while cleavage from the resin and removal of permanent protecting groups is usually accomplished with anhydrous hydrofluoric acid or other strong acid. The Fmoc strategy is a milder orthogonal approach in that the two classes of protecting groups are removed by different chemical mechanisms such that either class can be removed while preserving the other class. The temporary Fmoc group is removed by a base-catalyzed β-elimination mechanism, usually employing piperidine. Removal of permanent protecting groups as well as cleavage from the support is accomplished by acidolysis, usually with trifluoroacetic acid.

Formation of the peptide bond between the carboxyl group of the incoming amino acid and the amino group on the peptide-resin requires that the carboxyl group be activated chemically. There are currently four major coupling strategies that utilize either active esters, preformed symmetrical anhydrides, acid halides, or generation of the activated acid *in situ* with a variety of different reagents.

Peptides modified at the α-amino group can be easily produced by treatment with an acylating agent, such as acetic anhydride, prior to removal of the permanent protecting groups. Resins are also available for both Boc and Fmoc strategies that will directly yield peptides with either a free acid or an amide function at the carboxy-terminus.

In some instances, larger peptides have been formed from smaller ones by the use of segment condensation and chemoselective ligation techniques. In either case, two or more smaller peptides are synthesized in such a way that they can subsequently be linked together to form a large peptide. However, these procedures are not common and are still relatively difficult to perform.

5 Evaluation

Although the synthesis of any given peptide is often considered routine and can be performed with standard protocols on automated instruments, the chemistry used to produce synthetic peptides is complex and can be influenced by a number of factors that cannot always be foreseen or controlled. As a result, one must never assume that the final product is correct until it is proven to be so.

Homogeneity of the product and correct covalent structure are the two main aims in the production of synthetic peptides. The initial product obtained from the

stepwise solid-phase peptide synthesis will contain a variety of by-products in addition to the desired peptide. These products usually consist of deletion sequences generated during synthesis, and chemically modified peptides generated either during synthesis or during the cleavage and deprotection step. A successful synthesis is one in which these products are minimal and the intended peptide is present in sufficient yield to allow its purification from the mixture. Today, virtually all peptide purifications can be accomplished by high-pressure liquid chromatography (HPLC) using either reverse-phase or ion-exchange columns.

A common problem encountered in peptide synthesis is the production of deletion sequences. These come about as a result of either incomplete coupling or incomplete deprotection at any given cycle. Incomplete coupling of the incoming amino acid leaves a free α-amino group on the peptide chain that will persist into the next cycle and be able to couple with the next incoming residue. Incomplete deprotection results in the retention of a protected α-amino group that can subsequently be deprotected in the next cycle and thus be able to receive the incoming amino acid at that cycle. Both cases result in a finished peptide that is missing one amino acid residue. Deletion sequences due to incomplete coupling are probably the most common and the easiest to manage. The elongation of deletion peptides due to incomplete coupling can be halted by the use of a capping step. Capping simply refers to the reaction of the free α-amino group remaining at the end of a coupling step with a reagent such as acetic anhydride that derivatizes the α-amino group in such a way that it can no longer be elongated during subsequent cycles. Although capped peptides represent contaminants that will have to be removed from the final product, they are generally easier to separate from the full-length product than are deletion peptides, which may differ from the full-length product by only one amino acid.

Unwanted chemically modified peptides result either from incomplete deprotection of the side chains or from random adducts formed at some point during synthesis or cleavage and deprotection. As long as they do not represent an overwhelming proportion of the total product, they can usually be separated from the desired product without the need to identify their structure. When unwanted side-products show up as major species, either the chemical protocol or instrument operation needs to be checked and modified. In this regard, it is important to note that the isolation of a single major product from a synthesis does not guarantee that it is the intended product. Facile modifications are not uncommon and there are many instances in which the wrong peptide was isolated and used in experimentation because its structure was not verified.

There are numerous analytical techniques available for the evaluation of synthetic peptides. The techniques that have been commonly used include analytical high performance liquid chromatography (HPLC), capillary zone electrophoresis (CZE), amino acid compositional analysis, UV spectroscopy, sequence analysis, and mass spectrometry.

Today, mass spectrometry is most often used as the primary means of characterizing synthetic peptides. Efficient characterization of synthetic peptides is best obtained by a combination of analytical reverse-phase HPLC and mass spectrometry. Analytical reverse-phase HPLC provides evidence for the homogeneity of

the peptide product by presenting a picture of the number of peptide species present based on their chromatographic elution characteristics. Multiple peaks indicate heterogeneity and the area under the peaks is an indication of the relative amounts in each peak. Note, however, that a single main peak suggests relative homogeneity but does not exclude the possibility of comigrating species. Both electrospray ionization mass spectrometry (ESMS) and matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) can be used for the accurate determination of peptide mass. The position of modifications and deletions, if present, can be identified by sequencing with either chemical methods (Edman chemistry) or tandem mass spectrometry. In this respect, sequencing is most easily accomplished by collision-induced decomposition on ion-trap or tandem instruments such as Quadrupole-Time of Flight (Q-TOF) instruments. Amino acid analysis is the best technique for the quantitation of the product. It specifically measures the amount of amino acids present and is accurate to within ±5 to 10%. Gravimetric techniques will also measure the amount of salt and adsorbed water present in the peptide preparation. This can be substantial, up to 50% of the total, thus causing as much as a twofold error.

6
Applications and Perspectives

Peptides have become an important class of molecules in biomedical research and medicinal chemistry. Already a number of synthetic hormones or their analogs have found use as therapeutic agents. Synthetic peptides show great potential in being effective in regulating such physiological processes as blood pressure, neurotransmission, reproduction, and endocrine functions, to name a few. Synthetic peptide substrates for enzymes such as proteases, kinases, and phosphatases have been used successfully to study enzyme kinetics and mechanism and develop effective inhibitors. Synthetic peptides are seeing great success as antigens for the preparation of polyclonal and monoclonal antisera and offer the potential for more effective vaccines. The process of *de novo* drug discovery is enhanced through the development of peptide libraries. Epitope mapping of proteins with synthetic peptides has identified regions important for biological activity. Synthetic peptides have been instrumental in receptor localization, characterization, and isolation. Finally, even whole enzymes have been produced by synthetic methods. A comprehensive discussion of the many and diverse uses for synthetic polypeptides is obviously beyond the scope of this article. Therefore, the following sections attempt to briefly present some of the more recent and interesting applications in the field.

6.1
Antigenic and Immunogenic Uses and Vaccines

The ability of synthetic peptides to immunologically mimic regions of whole proteins has resulted in their extensive use as antigens and probes of protein epitopes. Antibodies that are raised against a native protein bind to relatively small areas on the surface of that protein and can often recognize and bind to the same antigenic sequence in the absence of the rest of the protein. Thus, highly antigenic sequences or epitopes can be mapped in

proteins by synthesizing overlapping peptides, spanning the full sequence of the protein and testing them for binding of the antibody.

Many gene products have been identified and isolated by prediction of antigenic regions in the sequence of a protein that was initially deduced from a gene sequence. Synthetic peptides corresponding to these predicted antigenic regions are used to produce antibodies that in turn are used to specifically interact with the intact protein product for identification and isolation. Although this approach has proven very successful, the main problem in its implementation is the prediction of the protein's antigenic sequences. Although there is no guarantee of success, certain general guidelines for choosing surface epitopes have been described. First, use of a hydropathy profile locates areas that are more hydrophilic. This is based on the assumption that the surface of a protein is exposed to solvent and will thus be hydrophilic in nature. If you only have a short section to work with, choose areas that are charged or polar. In general, the immediate amino and carboxyl ends of a protein may tend to be more solvent accessible than the interior sequence. These regions may be better candidates if you have no other criteria. Secondly, since short stretches of sequence in proteins do not have exposed termini that can become charged, synthesize the peptide with α-amino and α-carboxyl blocking groups such as N-terminal acetyl groups and C-terminal amide groups. Keep in mind that the peptide must be sufficiently polar to be soluble in aqueous solution. Peptides of 10 to 15 residues are usually adequate for the production of antibodies, and including a cysteine residue at either end can be helpful for cross-linking to carrier proteins via heterobifunctional cross-linking reagents (see Fig. 5). The use of a carrier protein is usually necessary because small peptides, in general, are not sufficiently antigenic to produce an immune response on their own. This is because they generally lack T-cell epitopes that can be provided by the carrier. Antibodies are produced by B-cells that recognize or respond to certain epitopes. T-cells also recognize epitopes, but these epitopes are different from those recognized by B-cells. In the presence of T-cell epitopes or antigens, T-cells stimulate B-cells to boost their antibody production. Thus, to produce a good antisera, both B- and T-cell epitopes should be present.

In addition to linking polypeptide antigens to carrier proteins, two purely synthetic approaches have also been shown to be successful in producing antisera (Fig. 5). One approach, using the concept of a template-assembled synthetic protein (TASP) involves synthesizing both B- and T-cell peptide epitopes as branches on a β-sheet peptide backbone template. Another approach, known as the multiple antigen peptide system (MAPS), uses a peptide core of radially branching lysine residues covalently connected to a conventional solid support for peptide synthesis. Peptide antigen sequences are built on the α- and ε-amino groups of the terminal multiple lysine residues. The resultant structure consists of multiple, tightly packed peptide antigen sequences on a single structure. Although no apparent T-cell epitopes are present, MAPS antigens have been shown to produce a strong immunogenic response that results in high titer antisera for the peptide antigen. This is thought to be due to the local high concentration of peptide presented.

One very exciting area that is based on the use of synthetic peptides as antigens is in the development of vaccines.

Synthetic peptide-based vaccines are actively being pursued as potential antiviral, antibacterial, and antiparasitic agents for such diseases as foot-and-mouth disease, poliovirus, hepatitis B, influenza, HIV, feline leukemia virus, malaria, diphtheria, and cholera to name a few. Prevention of some carcinomas, such as melanoma, is also being explored by this technique on the basis of segments of melanoma cell specific proteins that are presented antigenically to the host's immune system. These vaccines are based on the observations that viruses and microorganisms present major, protein-derived antigenic determinants on their surfaces, that many bacterial diseases stem from protein or peptide toxins secreted by the bacteria, and that cancer cells express antigens that are recognized as foreign to the host. If effective antisera can be raised against these regions, they have the potential to

neutralize the virus or toxic agent. Major impediments to developing effective peptide-based vaccines are the inability to definitively recognize the proper determinants to be used as a basis for the synthetic peptide antigen and the problem of serological diversity. With viruses, for example, selecting peptides that will be effective as vaccines is more difficult than just developing antibodies that will react with viruses. Virus particles possess a large number of different epitopes, but not all will produce antibodies that will neutralize virus infectivity. Even when a major neutralizing epitope is identified, diversity within that epitope can be a major problem. For instance, foot-and-mouth disease virus has as many as seven different serotypes throughout the world, and vaccination with one does not necessarily protect against the others. This is exacerbated by the fact that variation can exist within each serotype; many viruses display a much larger number of serotypes, and some display the ability to mutate fairly rapidly. However, if invariant regions can be found among the various subtypes, the number of synthetic peptide-based vaccines needed to protect against the agent can be reduced and vaccine development becomes feasible. The prospect of developing vaccines from synthetic peptides has the distinct advantages that the antigen is chemically well defined, relatively stable, and is free from possible biological contamination that can be a major problem with vaccines from biological sources.

6.2 Antisense Peptides

The area of antisense peptides is very new and still the subject of controversy that stems mainly from the fact that the experimental observations have not yet been adequately explained theoretically.

An antisense peptide is a peptide whose sequence is deduced from the nucleotide sequence that is complementary to the nucleotide sequence which codes for a naturally occurring peptide. In general, although it has not been shown to be the case in all instances, antisense peptides have shown selectivity in binding to their sense counterparts and have displayed unusual or surprising biological activity.

The basis for the unusual interaction between sense and antisense peptides appears to stem from the genetic code. In general, the codons for hydrophobic or hydrophilic amino acids on the coding strand of DNA are complemented by codons for hydrophilic or hydrophobic amino acids, respectively, on the opposite strand. Furthermore, reading of the complementary DNA strand in either direction displays the same pattern of hydrophobicity in the resultant amino acid sequence since the middle base of the codon seems to specify the hydropathic nature of the amino acid.

One of the most stunning successes in the use of antisense peptides is the demonstration that antibodies raised against an antisense peptide of adrenocorticotropin hormone (ACTH) were successful in recognizing and purifying the ACTH receptor. In other words, the antibodies, acting like an image of an image, interacted with the receptor in a manner similar to ACTH. Although many other similar successes have been reported, it is important to note that many failures have also been seen. Thus, the exact nature of the interaction is not well understood but the area of antisense peptides continues to be an exciting and growing field.

6.3 Peptide Libraries

The process of developing new synthetic peptides that are useful for diagnostic or therapeutic purposes usually involves the costly and time-consuming process of synthesizing hundreds of peptide analogs based on the structure of an original active peptide. In spite of recent advances that have improved this process, the task of screening all possible combinations of even short peptides has been impractical. For instance, there are 64 000 000 possible hexapeptides (20^6) for all combinations of the 20 naturally occurring protein amino acids.

Recently, the development of synthetic peptide libraries has greatly aided this task. Basically, the libraries are generated by synthesis of a mixture of a large number of peptides of defined length in which each position, or a defined number of positions, contains a random mixture of amino acids. These heterogeneous mixtures are then screened with some appropriate assay system, and the reactive sequences are isolated and determined. Several different methods for the generation and screening of synthetic peptide libraries have been described.

6.4 Other Applications

One approach to identifying, locating, and isolating receptors to polypeptide ligands such as peptide hormones and opioids is to establish chemical cross-links between the peptide ligand and the receptor subsequent to their binding. An ever-increasing number of heterobifunctional cross-linking reagents, many with photoactivatable reactive groups for *in situ* activation, are being developed for this purpose which can be attached to the biologically active peptides at a variety of locations. Once attached to the peptide, these reagents are capable of producing covalent cross-links between the peptide and the receptor. If the synthetic peptide is labeled, the label can be followed in isolating the receptor and identifying the area of contact in the peptide – the receptor complex.

Peptide nucleic acids are compounds that are synthesized with a peptide-like backbone with DNA- and RNA-derived bases as side chains (**X**). These polyamide oligomers appear to be capable of invading the duplex strand of DNA at specific locations determined by the identity of the bases, causing displacement of one strand, and disrupting transcription elongation of that stretch of DNA. As such, they display potential as antisense and antigene agents that may be superior to some phosphodiester backbone-based antisense agents with regard to stability and bioefficacy.

The use of peptidomimetics is a relatively new but growing area related to the field of synthetic polypeptides. Although the mimetic structure is often not strictly a peptide because it may completely lack peptide bonds, the structure is based on that of a peptide. Since the three-dimensional shape of a peptide determines how it will interact with its biological target, producing specific stable conformations in synthetic peptides is one of the most challenging areas in the design of biologically active peptides. In general, small peptides tend not to exhibit stable or even preferred conformations in solution. The general idea with peptidomimetics is to synthesize a compound that mimics some structural or conformational property that a peptide might assume biologically or that mimics some stable, relatively rigid

structure found in proteins, such as β- or γ-turns. The approach in synthesizing peptidomimetics is usually to replace part or all of the normal peptide structure with nonpeptidelike chemical structure so that the resulting conformation is stabilized and mimics the original peptide in space. The final mimic often has very little chemical resemblance to the peptide, but displays stable three-dimensional elements of conformation which is similar to that assumed by the peptide. Some approaches that have been taken in this regard have been to replace peptide bonds with rigid structures that maintain bond distance and side chain orientation or introduction of intramolecular cross-links to stabilize turns or side chain positions.

The area of peptidomimetics has been very actively pursued in rational drug design and pharmaceuticals. Although success has been limited owing to the difficulty in accurately mimicking the exact active biological conformation, some advances have been made and will no doubt continue since peptidomimetics have many potential applications. One successful example is the design of a tricyclic, conformationally constrained lactam that is among the most potent angiotensin converting enzyme (ACE) inhibitors known.

Finally, whole, biologically active proteins have been produced by purely synthetic methods. One striking example of this is the complete chemical synthesis of the human immunodeficiency virus-1 (HIV-1) protease that possesses full biological activity. Even more striking is the demonstration that the HIV-1 protease synthesized from all D-amino acids displays specificity for substrates with opposite chirality to the natural substrate.

The above sections only touch on some of the diverse and potentially very useful applications of synthetic peptides. From what has been accomplished with synthetic polypeptides already, it seems clear that they will continue to play an increasingly larger role in biomedical research and in the treatment of human, animal, and plant disease.

Keywords

Cell Cycle
A series of phases, designated G1, S, G2, and M, that a cell sequentially passes through between the time it is formed by cell division and the time it itself divides.

Chalones
Proposed soluble factors produced locally by an organ as it develops that act to limit further growth of that organ once it reaches its appropriate size.

Clone
Generally, a population of cells derived from a single cell by mitosis.

Embryonic Induction
A developmental phenomenon wherein one part of the embryo determines the fate of another part of the embryo.

Embryonic Stem (ES) Cells
Stem cells derived from the embryo.

Growth Factors
Extracellular polypeptide signal molecules that can stimulate a cell to grow or proliferate.

Intracellular Signal Transduction
Cascades of chemical reactions used by cells to convey information from the cell surface to the interior of the cell (e.g. the nucleus) where the information is acted upon; the cell makes use of intracellular signal transduction pathways.

Organogenesis
Organ formation.

Pluripotent Cell
A cell that is capable of giving rise to several of the cell types of an organism.

Receptors
Proteins that bind other molecules or ions, and, as a result of the binding, influence cellular activity.

Reproductive Cloning
Cloning for reproductive purposes; that is, producing new organisms that are genetically identical to the donor of the nuclear material.

Stem Cell
A cell that undergoes mitotic cell division to give rise to the same type of cell; at some point, stem cells leave the pool of mitotically dividing cells to begin a process of cell differentiation.

Therapeutic Cloning
Transferring nuclear material from a donor somatic cell into an enucleated egg cell and harvesting embryonic stem cells (ESCs) from the resulting blastocyst.

Transcription Factors
Proteins that attach to DNA at a gene regulatory site and by so doing influence the rate of transcription of a specific gene.

Developmental cell biology is that part of biology concerned with the consequences of what cells do in the context of developing organisms. Developmental biologists are concerned with events before fertilization, for example, gametogenesis, and after birth (or its equivalent in nonmammalian species), for example, metamorphosis and regeneration. The range of species in the purview of the developmental biologist covers, essentially, the entire living world – animals, plants, protists, fungi, and even prokaryotes. Using the human example, cell proliferation is required to create the trillions of cells of which we are composed; cell differentiation provides the more than 200 different kinds of cells identified so far in the human body, and morphogenesis shapes the body form characteristic of the human species. Our understanding of the molecular and cellular mechanisms that underlie these phenomena has been progressing at an ever-increasing rate, a testimonial to the army of cell and developmental biologists at work across the planet. Understanding the regulation of the cell cycle, apoptosis, cell differentiation, cell signaling, cell signal transduction, and cell movement, to mention a few such phenomena; understanding the integration of their underlying molecular and cellular mechanisms; and understanding the developmental consequences of their operation, makes the early twenty-first century an exciting time to be a developmental cell biologist. It is also a hopeful time for those people suffering the ravages of dreadful diseases, such as cancer, and for those people awaiting the promise of regenerative medicine.

1 Historical Perspective

Recently, we have been reminded that cell biology involves investigation of the molecular basis of how cells work, whereas developmental biology is often concerned with understanding how processes are integrated to make the organism. Furthermore, even though the boundaries between cell and developmental biology are once again beginning to blur, differences still exist between cell and developmental biology and we have not returned to a situation in which cell and developmental biology completely overlap.

1.1 Origins of Cell Biology

The credit for the Cell Theory, of the early nineteenth century (1838/1839), is given to Schwann and Schleiden. According to Churchill, Matthias Schwann's cell theory was, above all else, an embryological theory of the fine structure of the body; normal differentiation of tissues and organs followed a normal *Entwicklungsgeschichte* (developmental history) of the constituent cells; abnormal growths and neoplasias followed an abnormal cellular *Entwicklunsgeschichte*. It was no accident that both Schwann and Müller (Johannes Müller, German physiologist and comparative anatomist) quickly saw the implications of the cell theory for human pathology. During the middle of the same century, Rudolph Virchow laid the foundation for cellular pathology, replacing humoral pathology, which for centuries was purported to explain disease states. During the last quarter of the nineteenth century, the fundamental details of mitosis and meiosis at the light microscope level were accumulated.

1.2 Origins of Developmental Biology

The nineteenth century also saw the laying of the foundations of descriptive and comparative embryology, and the end of the same century provided the beginnings of experimental embryology.

Karl Ernst von Baer (1792–1876), an Estonian naturalist and pioneer embryologist, is considered by some to be the father of modern embryology. He first described the mammalian egg (1827), and, with his microscope, he could see that the mammalian egg was an undifferentiated mass containing no preformed creature. He believed that the mature egg, or the early developing embryo, possesses certain definite areas having different qualities, each of which contributes to the formation of a particular structure or several structures (1828, 1837). Von Baer became the first to trace the egg to the embryo.

In 1828, he published the *Epistle*, in which he originally set forth his discovery of the ovum and *Uber Entwickelungsgeschichte der Tiere* (Developmental History of Animals), which became a standard text of embryology. Four major advances in embryology were included in this book: (1) the discovery of the mammalian ovum, (2) the germ-layer theory, (3) the law of corresponding stages in the development of the embryo, and (4) the discovery of the notochord.

Also regarded as the father of comparative embryology, he was the first to make embryology truly comparative. Together with Pander (Christian Pander, Russian zoologist, regarded as a founder of the science of embryology), he formulated the germ layer concept as a structural fact for vertebrate embryology. Karl Ernst von Baer's *Development of Animals* (*Entwickelungsgeschichte der*

Tiere – Beobachtung und Reflexion) added the final stroke against the preformation doctrine; he showed differentiation to be a progressive process. Von Baer enriched embryology in three directions: (1) he set a higher standard for all work in embryology and lifted the science to a higher level, (2) he established the germ layer theory, and (3) he made embryology comparative. For a long time after von Baer, the aim of embryologists was to trace the history of the germ layers.

According to Hickman, the very tiny ova of mammals escaped de Graaf's (Regnier de Graaf, seventeenth-century Dutch embryologist, after whom the Graafian follicle is named) eyes, but von Baer brought mammalian reproduction in line with that of other animals by detecting the ova and their true relationship to the follicles. One of the first achievements of the greatest embryologist of all time was this important discovery.

Again, according to Hickman, von Baer developed the biogenetic law, which states that the embryos of higher and lower forms tend to resemble each other more closely the further one goes back in their development. In comparing corresponding stages in the development of different kinds of embryos, von Baer advanced four propositions, which together became incorporated in the biogenetic law: (1) in development, general characters appear before special characters, (2) from the more general characters are developed the less general and finally the special, (3) in the course of development, an animal of one species diverges continuously from that of another, and (4) a higher animal during development passes through stages that resemble stages *in the development of* lower animals. This is a conservative and sounder conception of the biogenetic law than that of Ernst Haeckel (German embryologist), because von Baer did *not* maintain that the embryos of higher forms resemble the *adults* of lower organisms. Von Baer did not relate these observations to evolution; Haeckel (1834–1919) made the connection and popularized the phrase "ontogeny recapitulates phylogeny."

Wilhelm Roux (1850–1924), a German embryologist and a student of Haeckel, is considered to be a pioneer in (and by some, the founder of) experimental embryology.

Roux visualized a complex machine already functional in the fertilized egg, which suggested preformation. To be transmitted from cell to cell, Roux reasoned, the machine must in some way break down into its component parts during the process of cell division so that the parts can be transmitted to another cell, and reassemble there in some way and again become functional.

On the basis of his experimental evidence, of rotating eggs in their gravitational field and finding that the eggs develop normally, Roux concluded that eggs are self-differentiating rather than being driven by external conditions. By 1885, Roux was generating a general theory about the causes of embryonic development based on his idea of self-differentiation. He suggested that the nucleus holds all of the qualities for individual formation offering a theory of qualitative cell division, that is, each division actually separates off differential nuclear materials into different daughter cells; he said, the process is like producing a mosaic.

In the early 1890s, E. B. Wilson worked with the German embryologist Hans Driesch at the Zoological Station in Naples. Wilson, Driesch, and others did not gravitate toward Roux's emphasis on nuclear division to explain development; rather, they continued to look at the internal structure and the patterns of cell division

for clues to the causes of embryonic differentiation. Wilson (1904) carried out isolation experiments with *Patella coerulea*, a mollusc, and found that the blastomeres possess within themselves all the factors that determine (1) the form and rhythm of cleavage and (2) the differentiation that they undergo, wholly independent of their relationship to the remainder of the embryo. He also carried out experiments (1904) where he removed polar lobes from *Dentalium*, a mollusc, and determined that its mosaic development was based on the segregation of specific morphogenetic determinants into specific blastomeres; for example, Wilson concluded that the polar lobe cytoplasm contained the mesodermal determinants. August Weismann came to conclusions similar to those of Roux, but went on to offer a larger theory of development. Weismann's theory was based on the assumption that physical hereditary units exist within the nucleus and he postulated a mechanism for the separation of those units.

Roux's famous experiments, the so-called half-embryo experiments (1888), which seemed to demonstrate preformation, were carried out by killing, with a hot needle, one of the two blastomeres of a frog embryo; only one half of an embryo developed and Roux concluded that determination had already occurred in the two-cell stage. He recognized that his view was the leading alternative to Eduard Pflüger's (German physiologist 1829–1910) hypothesis that external conditions cause differentiation.

The goal of Hans Driesch (1867–1941) was to reduce embryology to the laws of physics and mathematics. He carried out *isolation* experiments (1892) with sea urchin embryos; he isolated blastomeres from the 2-cell, 4-cell, and 8-cell stages and found that individual isolated blastomeres developed into complete larvae; this result was not expected from the early experimental work of Roux.

Roux inaugurated (1894) the physiological approach to embryology (*Entwicklungsmechanik*, developmental mechanics). He insisted that embryology would no longer be the servant of evolutionary studies, but, rather, embryology would assume its role as an independent experimental science. He believed that many of the conclusions drawn from the investigation of ontogeny (development) would throw light on the phylogenetic (evolutionary) process. Roux implied that he considered experimentation the only legitimate method for biological science. He founded his own new journal, *Wilhelm Roux's Archiv für Entwicklungsmechanik der Organismen* (*Roux's Archives of Developmental Biology*), in which he was noted for exercising a heavy editorial hand. Roux himself, in 1881 had, in *Der Kampf der Theile*, expressed the idea of mutual interaction between embryonic parts.

Hans Spemann (1869–1941), a German zoologist was the 1935 recipient of a Nobel Prize in Physiology or Medicine for his discovery of the organizer effect in embryonic development. He wrote the classic book, *Embryonic Development and Induction* (1938). According to Saha, although Spemann was not the first scientist to introduce the concept of induction into embryological thought, he, in the course of his lens induction studies, popularized and refined the concept, rendering it as one that might serve as a unifying principle for vertebrate development.

1.3 Relationship between Cell and Developmental Biology

Albrecht von Koelliker (1817–1905) traced the origin of tissues from the segmenting

ovum through the developing embryo. He encompassed the whole field of embryology and published, in 1861 and again in 1876, a general treatise on vertebrate embryology of high merit. He is said to have done more to establish the cell theory than anyone else; he was one of the first to recognize the ovum as a cell (1840, doctoral thesis) and the first to point out that spermatozoa were cells. He earned his doctorate with work that traced the development of spermatozoa from stem cells to their release from the testes (1841). His *Entwicklungsgeschichte* was the first book on comparative embryology; it was he who first applied the cell theory to embryology.

The German biologist, August Weismann (1834–1914), one of the great synthesizers of biology, in 1887, recognized that the doubling of the chromosome number that occurs in fertilization would lead to unmanageable numbers of chromosomes unless a means was at hand to counteract this buildup (meiosis, of course, is that process). He proposed the first testable alternative to Darwin's theory of pangenesis. In 1883, Weismann proposed the germplasm theory, which maintained that different nuclear determinants entered different cells, and only in the nuclei of germ cells were all types of determinants retained. His hypothesis proposed continuity of the germplasm, diversity of the somatoplasm, and that the germ line was totally independent of the somatic cells. E. B. Wilson claimed that his classic textbook grew out of Weismann's hypothesis.

Thus, by the dawn of the twentieth century, although not generally referred to as such at the time, cell biology and developmental biology were burgeoning disciplines of biology.

Early in the twentieth century, Edmund Beecher Wilson (1856–1939), an American zoologist, specializing in cytology and embryology, wrote *The Cell in Development and Heredity*, 3rd edition (1925). This book is correctly considered to be a classic in, at least, the fields of cytology (cell biology) and embryology (developmental biology). Testimonial to the classic nature of Wilson's book is the observation that it is still referenced early in the twenty-first century.

According to Gilbert, the experiments of Spemann and his students framed the questions that experimental embryologists asked for most of the twentieth century, and, further, the discoveries associated with these inductive processes have provided some of the most exciting moments in contemporary science.

In the editorial of the article, Where Cell Biology and Developmental Biology Meet, in the inaugural issue of the journal, *Developmental Cell*, **1** (1): 1, Siegel and Sweet propose that it really does seem as though we are beginning to understand how cells function, both individually and as part of multicellular organisms, and that there is growing interaction and overlap between cell biology and developmental biology.

The commentary by Dawes–Hoang and Wieschaus in the same issue of this journal (2001) suggests that the development of tissue culture techniques, initiated by Ross Harrison in 1910, enabled biologists to study cells *in vitro*, and that this further separated cytology from embryology and has remained an important difference between them. They further propose that, with a shift in interest from the structural composition of cells to the processes taking place within them and the molecular function of the components involved, cytology grew into the

field of cell biology; and with the success of genetic and molecular approaches coupled with a focus on the concepts of induction, patterning, and gene expression, embryology expanded into the intellectual discipline of developmental biology. They further propose that in areas where cell and developmental biology are successfully interfacing (e.g. the growth cone and signal transduction pathways), developmental biology is becoming increasingly more defined and molecular and cell biology has expanded to incorporate broader aspects of function for the proteins of interest.

Edward B. Lewis (USA) and Christiane Nüsslein-Volhard (Germany), and Eric Wieschaus (USA) were corecipients of the 1995 Nobel Prize for Physiology or Medicine for the discovery of genes that control the early stages of the body's development.

During the second half of the twentieth century, the merging of cell and developmental biology was reflected in the titles of books and journals (e.g. *Annual Review of Cell Biology* became *Annual Review of Cell and Developmental Biology*, *In Vitro* became *In Vitro Cell and Developmental Biology*), and, in 2001, Cell Press established a new journal, *Developmental Cell*.

Just as one endeavored to explain cellular phenomena at the molecular level, during the twentieth century it became increasingly clear that development needed to be explained at the cellular level, including not only intracellular signal transduction but also cell–cell communication and cell–extracellular matrix (ECM) interaction. Attempts to explain the mechanisms and control of cell proliferation, cytodifferentiation, embryo patterning, and morphogenesis necessitated molecular understanding.

2
Cell Activities Underlying Development

2.1
Intracellular Signal Transduction

Developmentally important cellular activities include cell division and differential gene expression; in a multicellular organism, these cellular activities, including signals from other cells, are under the control of the cell's environment. Although some of these signals, for example steroid hormones, are nonpolar and are able to pass through the plasma membrane of the cell, other signals are polar, for example, the hormone epinephrine, and attach to receptors in the plasma membrane. In order to convey information carried by the signal from the cell surface to the interior of the cell (e.g. the nucleus) where the information is acted upon, the cell makes use of cascades of chemical reactions that make up intracellular signal transduction pathways.

2.1.1 **Receptors**

Receptor proteins are proteins that bind other molecules or ions and as a result of the binding, influence cellular activity, for example, insulin receptors in the cell surface and progesterone receptors in the cytoplasm.

Androgen insensitivity syndrome is the result of a mutation in which XY individuals (chromosomally male) do not make a functional testosterone *receptor*. Testicular feminization is a result of a sex-linked mutation; tissues that normally respond to androgens (male hormones, primarily testosterone) do not and, as a consequence, affected individuals, although carrying the XY sex chromosome makeup, are phenotypically females.

EGF or epidermal growth factor receptors are tyrosine kinases and activate the MAP kinase pathway (an intracellular signal transduction pathway important in the control of cell growth and proliferation).

Enzyme-linked receptors are cell surface receptors (e.g. tyrosine kinases, serine/threonine kinases) found in plasma membranes, which upon binding their ligand (e.g. a paracrine factor) activate enzyme activity. These receptors are important in developmentally significant intracellular signal transduction pathways.

Ephrin proteins are the main proteins involved in *restriction* of neural crest–cell migration. Eph receptors are cell-surface receptors used by neural crest cells to recognize the ephrin proteins; binding of ephrin proteins activates the tyrosine kinase domains of the Eph receptors in neural crest cells; these kinases probably phosphorylate proteins that *interfere* with the actin cytoskeleton which is critical for cell migration.

The, now archaic, Fertilizin Theory of Fertilization held that the binding of fertilizin (from jelly coats of sea urchins) with antifertilizin (fertilizin receptors on the heads of sea urchin sperm) was the basis of species specificity in sea urchin fertilization.

Toll is a maternal gene in *Drosophila* that encodes a receptor protein, which is only activated in the future ventral region of the embryo, by a ligand, called the *spätzle fragment*, which is only produced in the ventral perivitelline space. Activation of the toll receptor generates a signal that causes a maternal gene product in the adjoining cytoplasm, the dorsal protein encoded by the *dorsal* gene, to enter nearby nuclei; this dorsal protein is a transcription factor with a vital role in organizing the dorsoventral axis of the embryo.

Torso is a maternal gene in *Drosophila* that plays a key role in specifying the structures at the extreme ends of the anteroposterior axis of the embryo (e.g. the acron at the anterior end and the telson at the posterior end). *Torso* encodes a receptor protein, which is uniformly distributed throughout the egg plasma membrane, but is only activated at the ends of the fertilized egg because the protein ligand for the receptor is present there only. The ligand for the torso protein, which distinguishes the termini, is synthesized and secreted by both posterior and anterior follicle cells, but not by other follicle cells.

Osteoprotegerin or osteoclastogenesis inhibitory factor is a member of the TNF receptor superfamily; together with its ligand, it regulates conversion of a macrophage stem cell into an osteoclast.

Retinoic acid receptors (RARs) is a group of transcription factors, active only when they have bound retinoic acid; the RARs bind to specific enhancer elements in the DNA called *retinoic acid response* elements. Some of the *Hox* genes have retinoic acid response elements in their promoters. Retinoic acid, a derivative of vitamin A, is a small-molecule-inducing factor, which can enter cells freely by diffusion; its receptor is itself a transcription factor, which upon binding retinoic acid, translocates to the nucleus to activate its target genes. Retinoic acid is a morphogen-controlling pattern formation in chick and amphibian limbs; it is also likely to play a role in posteriorizing the neural tube; and it has been shown to activate the expression of more posterior *Hox* genes. Homeotic changes are seen when mouse embryos are exposed to teratogenic doses of retinoic acid. Human infant anomalies caused by inadvertent exposure to retinoic acid include absent or defective ears, absent or small jaws, cleft palate, aortic

arch abnormalities, thymic deficiencies, and abnormalities of the central nervous system. Inside the developing embryo, vitamin A and 13-*cis*-retinoic acid become isomerized to the developmentally active forms of retinoic acid, *all-trans*-retinoic acid, and 9-*cis*-retinoic acid.

The nuclear receptor superfamily consists of transcription factors that are also intracelluar receptors stimulated by lipophilic ligands including steroids, thyroid hormones, and retinoic acid; they have a hormone-binding domain, a DNA-binding domain, and a transcription activation domain. The receptor is normally complexed with a heat shock protein called hsp90 and thereby retained in the cell cytoplasm; on binding the hormone, the hsp90 is displaced, and the factors can form active dimers that move to the nucleus and bind to target genes. Examples include the retinoic acid receptors and the ecdysone receptors.

RU-486 (mifepristone) is a synthetic steroid that blocks the progesterone receptor from binding progesterone, which stops the uterine wall from thickening and prevents the implantation of a blastocyst; used as an alternative to surgical abortion.

Downregulation is a reduction in responsiveness of a cell to a stimulus following the first exposure: this is often produced by a reduction in the number of available receptors expressed on the surface, which can result from internalization of the ligand–receptor complex or from decreased expression of the receptor, for example, the cell-surface receptors for several growth factors are internalized following the growth factor binding and are eventually degraded in lysosomes. The effect of this process is to remove the receptor–ligand complexes from the plasma membrane terminating the response of the cell to growth factor stimulation. Classically, the concept referred to hormone receptors but contemporary usage includes other cell-surface receptors.

Upregulation is a process that increases ligand–receptor interactions due to an increase in the number of available receptors; for example, EGF-induced upregulation of cyclin D1 protein in NIH 3T3(M17) fibroblasts.

A morphogen receptor gradient is a gradient of those molecules that recognize the morphogen; the expression of the *Brachyury* and *goosecoid* genes has been correlated with the number of activin receptors on each cell that binds activin.

2.1.2 Intracellular Signal Transduction

Signal transduction is converting a signal from one form to another, for example, converting a cAMP signal to a kinase signal as an intracellular signal transduction pathway progresses into the interior of a cell.

The JAK/STAT signal transduction pathway is an example of an intracellular signal transduction pathway that is important in development. This pathway is extremely important in the differentiation of blood cells and in the activation of the casein gene during milk production. The STAT pathway is very important in the regulation of human fetal bone growth.

The phosphoinositol pathway is a common intracellular signal transduction pathway. During sea urchin fertilization, when bindin (a ligand on the surface of the spermatozoon) binds to the bindin receptor on the surface of the egg, a G-protein is activated. The G-protein, in turn, activates the enzyme phospholipase C, which hydrolyzes its substrate, phosphatidylinositol bisphosphate (PIP_2) into two products, diacylglycerol (DAG) and inositol triphosphate (IP_3). The DAG activates protein kinase C, which in turn, activates a H^+/Na^+

exchanger, which by simultaneously transporting H^+ out of the egg and Na^+ into the egg, causes alkalinization of the egg's cytoplasm. Meanwhile, the IP_3 binds to a receptor on the membrane of the endoplasmic reticulum (ER), causing the ER to release Ca^{++} into the cytosol of the egg. Together, alkalinization of the cytoplasm and elevated Ca^{++} concentration in the egg cytoplasm cause activation of the egg.

The RTK (receptor tyrosine kinase) signal transduction pathway is an intracellular signal transduction pathway important in development and was one of the first pathways to unite various areas of developmental biology. In migrating neural crest cells of humans and mice, the RTK pathway is important in activating the microphthalmia transcription factor (Mitf) to produce pigment cells.

Another intracellular signal transduction pathway important in development is the Smad signal transduction pathway. In vertebrates, this pathway appears to be activated by the TGF-ß superfamily ligand nodal in those cells responsible for the formation of the mesoderm and for specifying the left–right axis in vertebrates.

An intracellular signal transduction pathway used in different cells in different ways is the Wnt-signal transduction pathway; additionally, its components can have more than one function in the cell; it is involved in segment polarity in *Drosophila*, axis formation in *Caenorhabditis elegans*, and in axis formation in *Xenopus*.

The hedgehog signal transduction pathway is an important pathway in limb and neural differentiation in vertebrates.

Phytochromes are plant pigments that transduce photoperiodic signals from the external environment.

Cross-talk interactions occur between seemingly independent intracellular signal transduction pathways, for example, cooperation between two pathways resulting in the formation of the AP-1 transcription factor, which turns on interleukin 2 transcription during lymphocyte differentiation.

Homologous signal transduction pathways are composed of homologous proteins arranged in a homologous manner. Homologous pathways form the basic infrastructure of development; however, the targets of these pathways may differ among organisms, for example, the dorsal-cactus pathway used in *Drosophila* for specifying dorsal–ventral polarity is also used by the mammalian immune system to activate inflammatory proteins. When homologous developmental pathways are used for the same function in both protostomes and deuterostomes, they are said to have deep homology.

2.1.3 Transcription Factors

A transcription factor is a molecule that attaches to DNA at a gene regulatory site and by so doing influences the rate of transcription of a specific gene; it is a protein that regulates the transcription of genes, often, but not exclusively, by binding to cis-regulatory elements (promoters and enhancers). Transcription factors come in two general types: basal transcription factors (e.g. TFIID, TFIIA, etc.), which attach to gene promoters, and cell-specific transcription factors (e.g. Pax6, Mitf, etc.), which bind to gene enhancers. Trans-regulatory factors are usually transcription factors. There are four major families of transcription factors: homeodomain, basic helix–loop–helix (bHLH), basic leucine zipper (bZip), and zinc finger.

The trans-activating domain of a transcription factor is that domain concerned with activating or suppressing the gene's transcription; activation domains

of transcription factors often contain many acidic amino acids forming an ''acid blob,'' which accelerates the formation of the general transcription complex.

A trans-regulatory factor is usually a soluble protein, produced at a gene distant from the chromosome region that it affects; they are usually transcription factors that bind to cis-regulatory elements (promoters and enhancers).

Transcriptional regulation is regulation of transcription of RNA from DNA, under the control of RNA polymerase, transcription factors, promoters, and enhancers. A transcription initiation complex is, collectively, the RNA polymerase and the associated basal transcription factors that attach to a gene promoter.

A battery is a group of genes regulated by the same transcription factor.

Zygotic genes are those genes expressed by the embryo itself, that is, the embryo's genes as opposed to maternal genes expressed in the embryo. In early *Drosophila* development, most of the zygotic genes, first activated along the anteroposterior and dorsoventral axes set up by maternal genes, encode transcription factors, which, then activate more zygotic genes.

Combinatorial regulation is the control of gene transcription by two or more transcription factors; the spatial patterns of gene expression are often delimited by the combined action of transcription factors.

Competence is the ability to respond to an inductive signal or the reactive state permitting development in response to a stimulus, as part of an embryo in response to an inductive signal, or the responsiveness to the signals that turn on the relevant combination of transcription factors.

Specification is the early part of commitment to cell fate, where the fate of a cell depends on environmental cues, but is flexible and can still be altered in response to environmental signals. Determination is the second part of commitment to cell fate; the fate of a cell has become cell-intrinsic and is irreversible; the cell's commitment to eventually differentiate into a specific cell type and no other (transdifferentiation or metaplasia is the transformation of one form of *adult* tissue to another, as seen for example in Wolffian regeneration). Blastomeres are determined by cytoplasmic segregation or by interactions among blastomeres. In a molecular sense, determination means that the cells have lost their responsiveness, or competence, to the signals that originally turned on the relevant combination of transcription factors.

The basic helix–loop–helix (bHLH) family is one of the four major families of transcription factors; transcription factors in this family function in muscle and nerve specification, for example, MyoD.

The homeodomain family is one of the four major families of transcription factors, including the Hox subfamily, which play an important role in axis formation, for example, Hoxa-1, Hoxb-2, and so on. The bicoid protein is a member of the homeodomain family of transcriptional activators and activates the *hunchback* gene by binding to regulatory sites within the promoter region.

The hunchback protein acts, in the *Drosophila* embryo, as a morphogen for the next stage of patterning. To establish a clear anteroposterior gradient of zygotic hunchback protein, nanoprotein inhibits translation of posterior maternal *hunchback* mRNA. The hunchback protein, itself a transcription factor, acts as a morphogen to which other gap genes respond.

The basic leucine zipper (bZip) transcription factors with a structure similar to that of bHLH proteins are dimers, each

of whose subunits contains a basic DNA-binding domain at the carboxyl end, followed closely by an alpha-helix containing several leucine residues. The two subunits of the protein interact through leucine-containing repeat sequences. CCAAT enhancer binding protein (C/EBP) is a bZip protein that can bind to the DNA sequence CCAAT; it plays a role in adipogenesis similar to that of bHLH proteins in myogenesis. The bZip family is one of four major families of transcription factors; transcription factors in this family function in liver differentiation and fat cell specification, for example, C/EBP, AP1, and so on.

The zinc finger family is one of the four major families of transcription factors and includes the nuclear hormone receptor subfamily; transcription factors in this family function in secondary sex determination, for example, glucocorticoid receptor, estrogen receptor, testosterone receptor, and so on. Zinc finger proteins constitute a distinct class of transcription factors in which a DNA-binding polypeptide loop or ''finger'' forms through a coordination complex of zinc with cysteine and histidine residues at the base of the loop. These transcription factors make up a large and diverse group of proteins, for example, Krüppel in the early *Drosophila* embryo, WT-1 in the kidney, and Krox20 in the rhombomeres of the hindbrain.

The *Pax* genes are a subfamily of homeobox genes in vertebrates, which contain a homeobox and another conserved domain known as paired; these genes encode transcription factors with various functions in development. *Pax6* is a transcription factor belonging to the homeodomain family, necessary for mammalian eye, nervous system, and pancreas development.

During the development of bilaterally symmetrical organisms, three axes arise: (1) the anteroposterior axis: in *Drosophila*, this axis is laid down in the egg, (2) the dorsoventral axis: in *Drosophila*, this axis is laid down in the egg, and (3) the proximodistal axis. In *Drosophila*, the anteroposterior axis becomes divided into a number of unique regions on the basis of the overlapping and graded distributions of different transcription factors; the patterning of the dorsoventral axis involves two gradients, one of the dorsal protein and one of the decapentaplegic protein, with high points at the opposite ends of the dorsoventral axis. Patterning along the dorsoventral and anteroposterior axes divides the embryo into a number of discrete regions, each characterized by a unique pattern of zygotic gene activity.

The anterior visceral endoderm is one of two signaling centers in the mammalian embryo; it works together with the node (Hensen's node, ''the organizer'') to form the forebrain; it expresses several genes necessary for head formation, including genes for transcription factors, *Hesx-1*, *Lim-1*, and *Otx-2*, and for the paracrine factor Cerberus. These two signaling centers in the mammalian embryo are responsible for creation of the whole body, for example, the node produces Chordin and Noggin and works together with the anterior visceral endoderm to form the forebrain.

Tbx4 is a transcription factor that appears to be critical in instructing chick limbs to become hindlimbs and Tbx5 is a transcription factor that appears to be critical in instructing chick limbs to become forelimbs.

Historically, the bicoid protein gradient provided the first reliable evidence for the existence of the morphogen gradients that had been postulated to control pattern formation. The bicoid protein is a transcription factor that acts as a morphogen;

it switches on certain zygotic genes at different threshold concentrations, thus initiating a new pattern of gene expression along the anteroposterior axis. The bicoid protein is a member of the homeodomain family of transcriptional activators and activates the *hunchback* gene by binding to regulatory sites within the promoter region. *Bicoid* mRNA is localized in the anterior end of the unfertilized egg of *Drosophila*; after fertilization, it is translated (bicoid protein is absent from the unfertilized egg) and the bicoid protein diffuses from the anterior end, forming a concentration gradient along the anteroposterior axis.

Developmentally important transcription factors have DNA binding sites by which they bind to specific sites on DNA.

ß-catenin, the major candidate for the factor that forms the Nieuwkoop center in the dorsal-most vegetal cells of the amphibian blastula, is a transcription factor that can associate with other transcription factors to give them new properties; the β-catenin/Tcf3 (a ubiquitous transcription factor) complex appears to bind to the promoters of several genes whose activity is critical for axis formation.

CBFA1 is a transcription factor that appears to be able to transform mesenchyme cells into osteoblasts; the *Cbfa1* gene is activated in mesenchymal cells by bone morphogenetic proteins.

2.2 Cell Signaling

Signaling between and among cells is necessary for the order, that is the organism, to emerge from the potential chaos, which is multicellularity. Signaling between cells of the anterior pituitary gland and the gonads orchestrates development of gametes, and signaling between cells may result in cell death known as *apoptosis*.

2.2.1 Juxtacrine Signaling

Juxtacrine signaling is a mode of cell–cell communication in which signaling molecules are retained on the surface of the signaling cell, and they interact with receptor proteins on adjacent cell surfaces, for example, interaction between bride of sevenless protein and its receptor sevenless.

Ephrins interact directly with the 14 known Eph receptors, but there is some specificity: ephrin-A ligands preferentially bind to EphA receptors and ephrin-B ligands to EphB receptors. The five ephrin-A ligands are anchored to the cell surface through a glycosyl phosphatidylinositol (GPI) moiety, whereas the three ephrin-B ligands are anchored through a transmembrane segment. Expression patterns of Eph receptors and ephrin ligands determine which ligands interact with which receptors in particular tissues. This in turn dictates the precise spatial arrangement of signal activation, given that receptor- and ligand-bearing cells must be next to each other for the ephrin/Eph receptor association to take place (juxtacrine signaling). The ephrin/Eph receptor interaction is unusual in other respects. Signals are propagated not only downstream of the Eph receptor but also downstream of the ephrin ligand. Through this bidirectional mode of signaling, two neighboring cells with distinct identities can reciprocally influence each other. Thus, for example, ephrin- and Eph receptor-bearing cells move away from each other to occupy distinct spatial domains and are prevented from intermingling, as seen in Fig. 1.

2.2.2 Autocrine Signaling

An autocrine growth factor is a growth factor that is made by the same cell (target

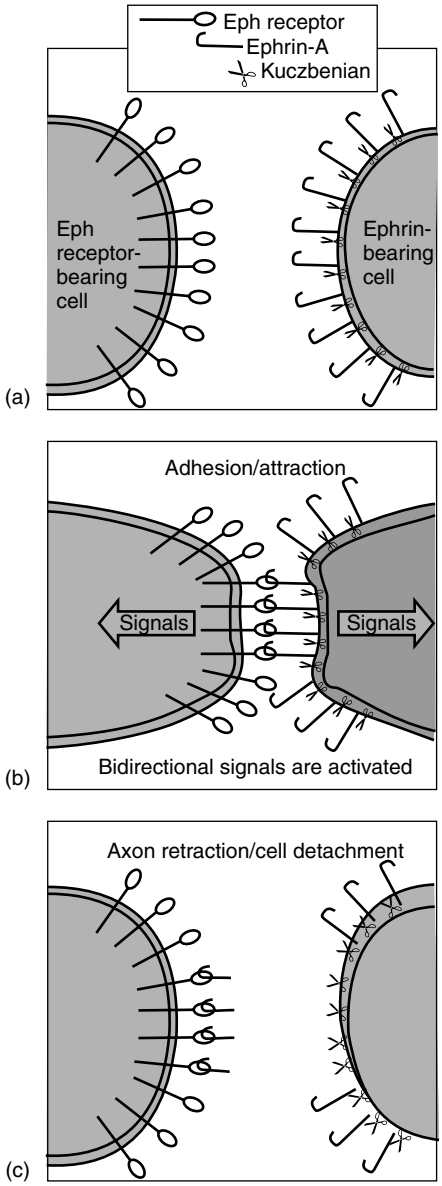

Fig. 1 Repulsive activities. (a) A cell bearing the Eph receptor comes into close proximity with an ephrin-bearing cell. (b) The receptor and ligand form multivalent adhesive complexes that transmit signals in both cells. (c) Some of these signals produce changes in the cytoskeleton that enable the two cells to pull apart after activation of the metalloprotease Kuzbanian and cleavage of ephrin. Pasquale (2000).

cell) that responds to it, for example, platelet-derived growth factor (PDGF). Transforming growth factor alpha (TGF-alpha) is an autocrine growth factor that stimulates development of the epidermis made by the basal cells and stimulates their own division.

It has been suggested that the HGF/SF (hepatocyte growth factor/scatter factor) could play a role in muscle development in an autocrine way. As a rule, HGF/SF is produced by mesenchymal cells, while its receptor, the tyrosine kinase encoded by the *met* proto-oncogene, is expressed by the neighboring epithelial cells in a paracrine fashion. They showed that both *HGF/SF* and *met* are coexpressed by undifferentiated C2 mouse myoblasts.

In growing cells, the autocrine loop is active as the receptor exhibits a constitutive phosphorylation on tyrosine that can be abrogated by exogenously added anti-HGF/SF neutralizing antibodies. The transcription of *HGF/SF* and *met* genes is downregulated when myoblasts stop proliferating and differentiate. The coexpression of *HGF/SF* and *met* genes is not exclusive to C2 cells since it has been assessed also in other myogenic cell lines and in mouse primary satellite cells, suggesting that HGF/SF could play a role in muscle development in an autocrine way. The autocrine loop needs to be downregulated during differentiation, since the constitutive activation of met kinase is incompatible with myogenesis.

The explosive proliferation of placental cytotrophoblast cells in response to PDGF, which these cells themselves produce, is an example of autocrine signaling.

2.2.3 **Paracrine Signaling**

Paracrine signaling is a mode of cell–cell communication in which signaling molecules (paracrine factors) act as local

mediators and only affect cells in the immediate environment of the signaling cell. These factors are the inducing factors of the classical experimental embryologists. Most paracrine factors fall into one of the four major families: Hedgehog, Wnt, TGF-ß, fibroblast growth factor (FGF). Keratinocyte growth factor (KGF), also known as FGF 7, is a growth factor needed for epidermal production, a paracrine factor produced by fibroblasts of the underlying dermis.

Stem cell factor (SCF) is a paracrine protein that promotes cell division in numerous stem cell populations; mice lacking SCF or its receptor (c-Kit protein) are sterile (no germ cells), white (no pigment cells), anemic (no red blood cells), and immunodeficient (no lymphocytes).

According to Pescovitz et al., spermatogenesis is a complex process that is both remarkable and enigmatic. While circulating hormones clearly play an important role in initiating and regulating the process, the Sertoli cell barrier prevents most substances from entering the seminiferous tubule compartment and directly influencing germ cell development. Therefore, the testis cannot rely solely upon the delivery of circulating hormones, nutrients, and growth factors, but must independently produce its own regulatory substances. A rapidly increasing number of testicular factors that appear to modulate spermatogenesis in a paracrine fashion are now being identified. These discoveries are beginning to contribute to our understanding of the intricate network of testicular cell–cell interactions that control male reproduction.

2.2.4 Endocrine Signaling

Endocrine signaling is a mode of cell–cell communication in which signaling molecules (endocrine factors/hormones) are released into the circulatory system and may affect cells (target cells) that are some distance from the signaling cell, for example, the effect of anterior pituitary gland hormones on the gonads. Endocrine factors are molecules (hormones) that function in endocrine signaling, for example, estrogens, testosterone, and progesterone. Cells that produce hormones are called endocrine cells and are often found in the endocrine glands, for example, pituitary glands, thyroid glands, and adrenal glands. Endocrine disrupters are exogenous chemicals that interfere with the normal function of hormones, for example, diethylstilbesterol.

2.2.5 Growth Factors

Growth factors are extracellular polypeptide signal molecules that can stimulate a cell to grow or proliferate. In the presence of growth factors, retinoblastoma protein (Rb), one factor maintaining the G_0 state of the cell cycle, becomes phosphorylated and hence deactivated. In the absence of Rb, a transcription factor called E2F becomes active and initiates a cascade of gene activation culminating in the resynthesis of cyclins, Cdks, and other components necessary to initiate the S-phase of the cell cycle.

Transforming growth factor ß (TGF-ß) is a family of protein growth factors, including the activins, bone morphogenetic proteins (BMPs), decapentaplegic protein (in *Drosophila*), and Vg1 protein (in *Xenopus*); their actions include potentiating or inhibiting responses of most cells to other growth factors, regulating the differentiation of some cell types, and acting as inductive signals in embryonic development. TGF-ß was originally discovered as a mitogen secreted by "transformed" (cancer-like) cells.

Activin is a member of the TGF-ß family of growth factors; it plays a key role in the induction of dorsal mesoderm in *Xenopus* embryos and is secreted by vegetal cells. Cytokines are growth factors that regulate blood cells and lymphocytes.

The cell-surface receptors for several growth factors are internalized following growth factor binding and are eventually degraded in lysosomes; the effect of this process is to remove the receptor–ligand complexes from the plasma membrane terminating the response of the cell to growth factor stimulation.

Apoptosis may be initiated by a withdrawal of growth factors from the cell or by an active response to a signal.

Fibroblast growth factor is a family of protein growth factors, first identified as mitogens for fibroblasts in tissue culture. FGF stimulates proliferation of many cell types, inhibits differentiation of various types of stem cells, and acts as inductive signals in embryonic development; for example, it plays a key role in the induction of ventral mesoderm in *Xenopus* embryos; it is secreted by vegetal cells.

The G_1 checkpoint is the checkpoint normally controlled by growth factors. In the absence of growth factors, the cell will leave the cycle and enter a state called G_0 in which Cdks and cyclins are absent.

The developmental pathway taken by the descendants of a pluripotential stem cell depends on which growth factors it is exposed to, which in turn is determined by the stromal cells to which it is exposed. Stem cells in the spleen become predominantly erythroid while those in the bone marrow become predominantly granulocytic. Stromal cells of the bone marrow create hematopoietic inductive environments (HIMs) by their ability to bind hematopoietic growth factors; without these growth factors, the stem cells die.

Insulin-like growth factor I (IGF-I) is a protein growth factor that promotes cell survival, stimulates cell metabolism, and collaborates with other growth factors to stimulate cell proliferation.

Platelet-derived growth factor is a protein growth factor that stimulates proliferation of connective tissue cells and some neuroglial cells; in angiogenesis, it is necessary for the recruitment of pericyte cells (mesenchymal cells found around a capillary). The explosive proliferation of placental cytotrophoblast cells in response to PDGF, which these cells themselves produce, is an example of autocrine signaling.

2.3 Cell–Cell Interaction

Cells may interact with each other in a variety of ways. In addition to cells interacting through cell signaling of the juxtacrine, autocrine, paracrine, and endocrine varieties, cells may make physical contact with each other through a variety of cell junctions, that is, tight junctions, gap junctions, and desmosomes.

2.3.1 Cell Junctions

Tight junctions are a type of adhering junctions typically found near the apical surfaces of epithelial cells. In addition to compartmentalizing parts of the multicellular animal body, tight junctions also create the necessity of transcytosis (movement of substances through, rather than around, cells) and by doing so, enable cells to regulate the passage of substances from one compartment into another.

Gap junctions are a type of communicating junction arising from organization of connexin proteins into conduits through which the cytoplasmic matrices

of neighboring cells establish continuity. Ions and small molecules may readily pass through these proteinaceous conduits, and provide the opportunity for metabolic coupling of the participating cells.

Gap junctions are collections of transmembrane channels that directly link the cytosols of two adjoining cells. They are present in almost all cell types of multicellular tissues in organisms ranging from mesozoa to humans, making them arguably the most ubiquitous and evolutionarily ancient form of intercellular communication in the animal kingdom. Hertzberg and coauthors (all leaders in the field) review recent progress in the identification and molecular characterization of the constituents of gap junctions, the determination of how gap junction channels are assembled and gated, and the elucidation of the myriad roles gap junctions play *in vivo*.

Desmosomes are like rivets holding adjacent epithelial cells together and, by doing so, provide the epithelium with structural integrity.

In a review article, Knust and Bossinger pointed out that although in recent years we have enormously increased our knowledge of the composition and formation of intercellular junctions in the epithelia of various organisms, we are still far from fully understanding the mechanisms by which the complex architecture of epithelial cells, or even the relatively simpler polarized organization of nonepithelial cells, is established and preserved. However, genetic and reverse genetic approaches in model organisms and extensive cell biological studies will be important in dissecting the sequence of events that promote the polarization of a cell. Complemented by data obtained from targeted gene inactivation experiments in the mouse, we will expand our knowledge of epithelial development and function. Additional information obtained from the analysis of other polarized cell types will further our knowledge of the process. Neurons, which transmit signals in one direction, migrating cells, and egg cells or embryonic blastomeres, which undergo asymmetric divisions, all rely on a polarized phenotype to fulfill their specialized tasks. The basic mechanisms used to establish and maintain polarization may be conserved and the same protein complexes may be used repeatedly to build different sorts of polarized cells.

2.3.2 Cell Signals

A pathway in the context of cell–cell signaling consists of the components required for sending, receiving, and transduction of a signal, including one or more ligands, membrane-associated receptors, intracellular signal transducers, and transcription factors.

2.4 Cell–Matrix Interaction

Growing, quiescent, and dying cells may all be found within the same microenvironment during morphogenesis. As it turns out, pattern formation is driven by differentials in cell growth and viability. The results of Chen et al. suggest that living cells can filter the same set of chemical inputs (activation of integrin and growth factor receptor signaling) to produce different functional outputs (growth vs apoptosis) as a result of local mechanical deformation of the cell or nucleus. By sensing their degree of extension or compression, cells may be able to monitor local changes in cell crowding or the extracellular matrix (ECM); (e.g. due to enhanced ECM remodeling or local application of cell tension) and thereby

couple changes in ECM extension to expansion of cell mass within the local tissue microenvironment. On the other hand, involution of tissue may be promoted in other microenvironments by inducing rapid breakdown of ECM and associated cell retraction. During malignant transformation, progressive loss of shape-dependent regulation may also lead to cell survival in the absence of ECM extension, unrestricted mass expansion, and hence neoplastic disorganization of tissue architecture.

2.4.1 Integrin Signaling

Cells reside in a protein network, the ECM, which they secrete and mold into the intercellular space. The ECM exerts profound control over cells. The effects of the matrix are primarily mediated by integrins, a family of cell surface receptors that attach cells to the matrix and mediate mechanical and chemical signals from it. As Giancotti and Ruoslahti point out, these signals regulate the activities of cytoplasmic kinases, growth factor receptors, and ion channels, and control the organization of the intracellular actin cytoskeleton. Furthermore, many integrin signals converge on cell cycle regulation, directing cells to live or die, to proliferate, or to exit the cell cycle and differentiate, as seen in Fig. 2.

Most integrins recognize several ECM proteins, and individual ECM proteins (e.g. fibronectin, laminins, collagens, and vitronectin) bind to several integrins. Integrins can signal through the cell membrane in either direction – extracellular binding activity of integrins is regulated from the inside of the cell, while the binding of the ECM elicits signals that are transmitted into the cell.

Adherent cells must be anchored to an appropriate ECM to survive; depending partly on signals from the matrix, they either proliferate or exit the cell cycle and differentiate. This anchorage requirement is lost in neoplastic cells. See Fig. 3.

The cytoplasmic domains of integrins always lack enzymatic activity, and thus, they transduce signals by associating with adaptor proteins that connect the integrin to the cytoskeleton, cytoplasmic kinases, and transmembrane growth factor receptors. Integrin signaling and assembly of the cytoskeleton are intimately linked. As integrins bind to ECM, they become clustered in the plane of the cell membrane and associate with a cytoskeletal and signaling complex that promotes the assembly of actin filaments. The reorganization of actin filaments into larger stress fibers, in turn, causes more integrin clustering, thus enhancing the matrix binding and organization by integrins in a positive feedback system (Fig. 2). As a result, ECM proteins, integrins, and cytoskeletal proteins assemble into aggregates on each side of the membrane. Well-developed aggregates detectable by immunofluorescence microscopy are known as *focal adhesions and ECM contacts*. Thus, integrins serve as integrators of the ECM and the cytoskeleton, as seen in Fig. 4, the property for which integrins are named.

2.4.2 Cell Movement

Cell shape changes and cell movements underlie the morphogenetic movements that create the form of the developing organism. Examples of the burgeoning literature on this topic are given in the published work of Keller, Adler, and Hall.

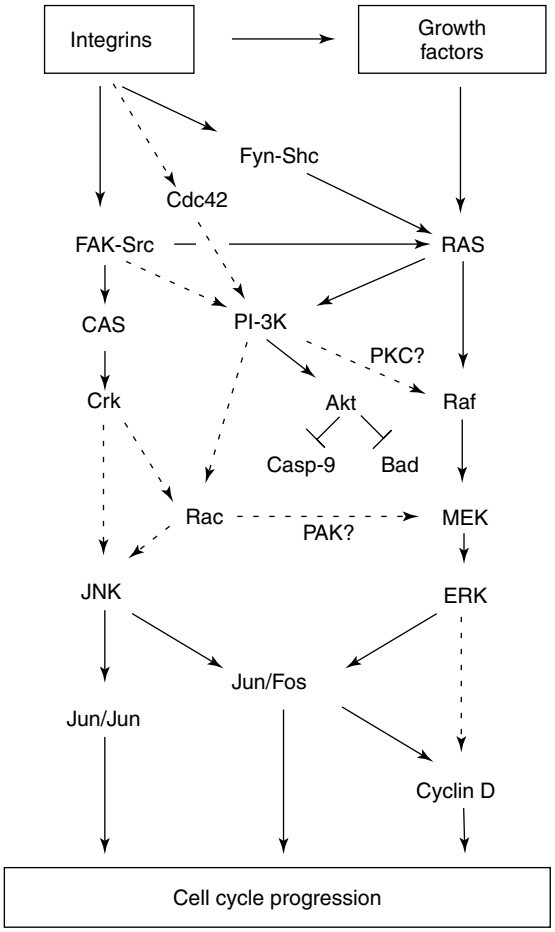

Fig. 2 Major signaling pathways that are known (solid arrows) or presumed (dashed arrows) to be coordinately regulated by integrins and growth factor receptors. These pathways control immediate-early gene expression, the cell cycle machinery, and cell survival. Giancotti and Ruoslahti (1999).

Polarized cell movements shape the major features of the vertebrate body plan during development. The head-to-tail body axis of vertebrates is elongated in embryonic stages by ''convergent extension'' tissue movements. During these movements, cells intercalate between one another transverse to the elongating body axis to form a narrower, longer array. Recent discoveries show that these polarized cell movements are controlled by homologs of genes that control the polarity of epithelial cells in the developing wing and eye of *Drosophila*.

A major breakthrough is the recent discovery that homologs of genes controlling the polarity of hairs on the epidermal cells of *Drosophila* wings also control the polarized cell motility underlying the morphogenic movements that shape the vertebrate body plan. These movements, known as *convergence and extension* or *convergent extension*, narrow (converge) the mediolateral aspect and elongate (extend) the anterior–posterior aspect of the vertebrate embryo, as seen in Fig. 5, and thereby establish its morphological and functional polarity, with

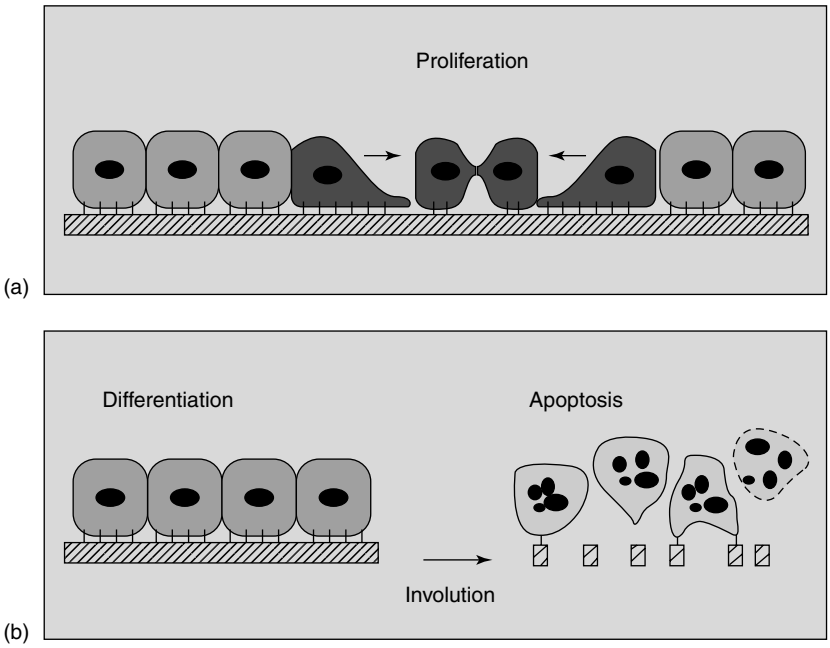

Fig. 3 Cell survival and cell proliferation require interaction with the extracellular matrix. (a) Epithelial cells in some tissues, such as skin and gut, are continuously renewed from stem cells that rest on a basement membrane. Neighboring cells migrate into the space left empty by cells that have moved away to differentiate. (b) Certain epithelia, such as those of the mammary gland and prostate, are not continuously renewed. In this case, interaction with the matrix appears to promote differentiation. During involution, the basement membrane is dissolved by proteolysis, and the cells undergo apoptosis. Giancotti and Ruoslahti (1999).

a head on one end and a tail on the other.

The polarity of cells within the plane of the epithelium of *Drosophila* is regulated by the planar cell polarity (PCP) pathway. This pathway controls the polarity of the single hair on each epidermal cell of the fly wing and the polarity of ommatidia in the compound eye.

Elements of the PCP pathway controlling epithelial cell polarity in *Drosophila* also regulate the polarized cell motility that shapes the body plan in vertebrates. This finding provides a genetic and molecular basis for a polarized cell behavior underlying the development of polarity at the level of the organism and thereby advances our understanding of the genetic encoding of the three-dimensional form. The cell biological mechanisms of how elements of the PCP pathway interact to build a form-generating machine are yet to be resolved.

The actin cytoskeleton mediates a variety of essential biological functions in all eukaryotic cells. In addition to providing a structural framework around which cell shape and polarity are defined, its dynamic properties provide the driving force for cells to move and to divide. Understanding the biochemical mechanisms

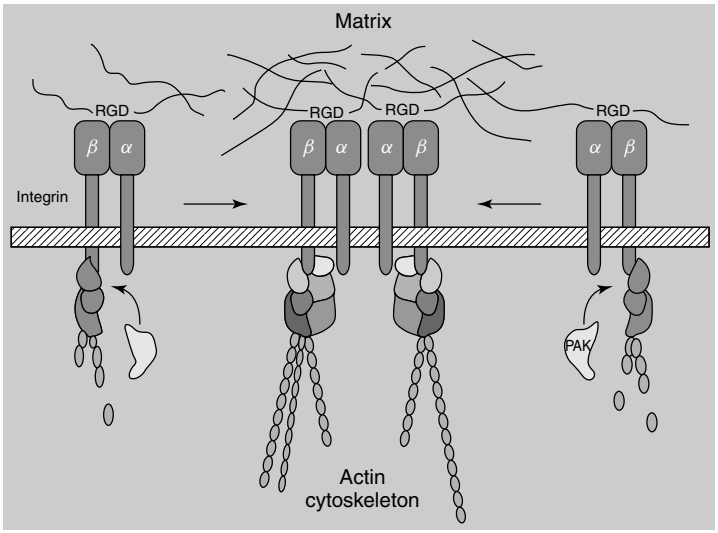

Fig. 4 Matrix binding promotes integrin clustering and association with the cytoskeleton. This in turn promotes further integrin clustering and matrix organization in a positive feedback system. RGD, Arg-Gly-Asp integrin-binding motif; Tal, talin; Pax, paxillin; Vin, vinculin; CAS, p130CAS. Giancotti and Ruoslahti (1999).

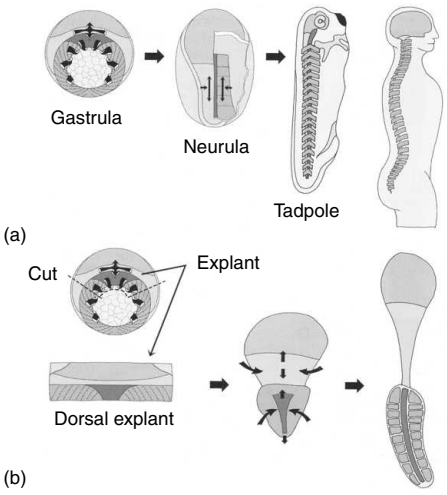

Fig. 5 Convergent extension movements elongate the anterior–posterior axis of the vertebrate body plan. (a) The notochordal (red) and somitic (pink) tissues turn inside, and converge (narrow) and extend (lengthens) in the gastrula and neurula stages of the frog embryo. The overlying presumptive hindbrain and spinal cord (blue) tissues converge and extend coordinately but on the outside of the embryo. These movements push the head away from the tail and elongate the body axis of the tadpole. Similar movements elongate the body axis of mammals. (b) Cultured explants of the same tissues also converge and extend, showing that convergent extension movements are driven by internal forces. Keller (2002). (See color plate p. xxiii.)

that control the organization of actin is thus a major goal of contemporary cell biology, with implications for health and disease. Members of the Rho family of small guanosine triphosphatases have emerged as key regulators of the actin cytoskeleton, and furthermore, through their interaction with multiple target proteins, they ensure coordinated control of other cellular activities such as gene

transcription and adhesion. Observations suggest that members of the Rho GTPase family are key regulatory molecules that link surface receptors to the organization of the actin cytoskeleton. See Fig. 6.

The JAK/STAT pathway is required in an unusually broad set of developmental decisions, including cell proliferation, cell fate determination, cell migration, planar polarity, convergent extension, and immunity. There is increasing evidence that the versatility of this pathway relies on its cooperation with other signal transduction pathways.

In a review, the components of the JAK/STAT pathway in model organisms and what is known about its requirement in cellular and developmental processes are discussed. In particular, they emphasize recent insights into the role that this pathway plays in the control of cell movement. In the past few years, studies from model organisms have established that the

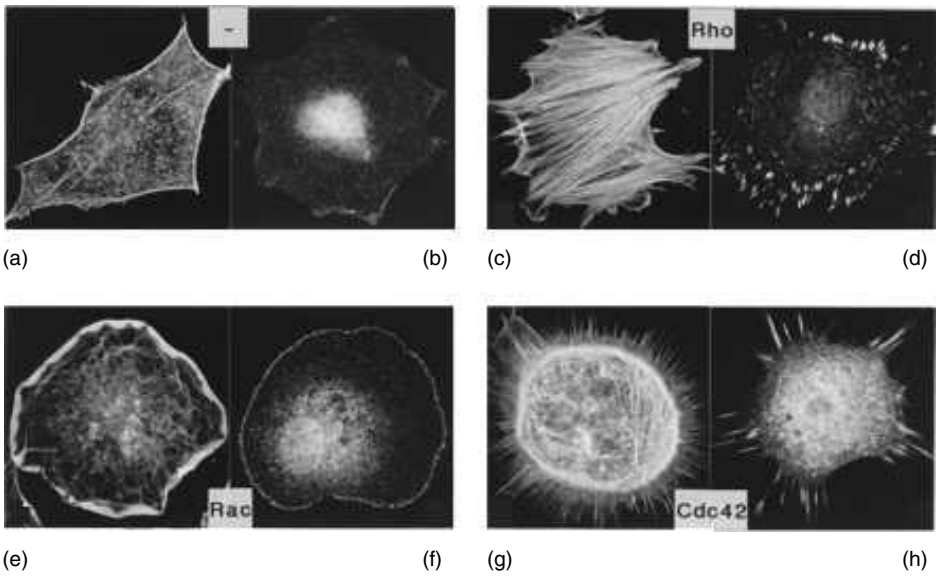

Fig. 6 Rho, Rac, and Cdc42 control the assembly and organization of the actin cytoskeleton. (a) Quiescent, serum-starved Swiss 3T3 fibroblasts (-) contain very few organized actin filaments or (b) vinculin-containing integrin adhesion complexes. The effects of Rho, Rac, or Cdc42 activation in these cells can be observed in several different ways such as with the addition of extracellular growth factors, microinjection of activated GTPases, or microinjection of guanosine diphosphate (GDP)–guanosine triphosphate (GTP) exchange factors. (c) Addition of the growth factor lysophosphatidic acid activates Rho, which leads to stress fiber and (d) focal adhesion formation. (e) Microinjection of constitutively active Rac induces lamellipodia and (f) associated adhesion complexes. (g) Microinjection of FGD1, an exchange factor for Cdc42, leads to formation of filopodia and (h) the associated adhesion complexes. Cdc42 activates Rac; hence, filopodia are intimately associated with lamellipodia, as shown in (g). In (a), (c), (e), and (g), actin filaments were visualized with rhodamine phalloidin; in (b), (d), (f), and (h), the adhesion complexes were visualized with an antibody to vinculin. Scale: 1 cm = 25 μm. (Figure courtesy, Kate Nobes).

JAK/STAT pathway is a central component of the signal transduction network that controls cell proliferation, fate, and movement. The outcome of JAK/STAT signaling in development depends on its collaboration with other signals and/or pathways. For example, during cell migration, the JAK/STAT signal may connect to the Rac/cytoskeleton pathway, and in the establishment of planar polarity, the JAK/STAT pathway cooperates with other pathways such as Wnt and N to produce a secondary signal.

Hou et al. ask the question, how can the same JAK/STAT pathway be used to produce completely different developmental outcomes in different tissue contexts? They then respond that the answer to this question will require an understanding of the array of transcription factors and molecules expressed in specific cells (history of the cell) as well as a description of the multiple signals received by a single cell (combinatorial signaling). Characterization of the genes that are regulated by JAK/STAT as well as the identification of signaling pathways that cooperate with JAK/STAT signaling are promising avenues toward understanding how this pathway can be involved in such a wide array of functions. See Fig. 7.

2.4.3 **Tubulogenesis**

Many organs of the body, for example, kidneys and testes, have a tubular nature. It is not surprising, therefore, that a burgeoning area of developmental cell biology would be the origin of tubulogenesis. The following information is taken from a recent review of tubulogenesis, in which specific references may be found.

Regarding the cellular events in tube formation, initial investigations of the cell biology of tubulogenesis suggested that the cellular mechanisms of tube formation might be as diverse as the gross differences in morphogenesis implied.

One of the earliest and most intensively studied systems, primary neural tube formation in chicks, pointed to the importance of cell shape changes. The first morphological event is the elongation of cells in the apicobasal dimension, with subsequent apical narrowing and basal expansion to create wedge-shaped cells that promote epithelial bending and wrapping. This and other investigations of epithelial morphogenesis led many to focus on cytoskeletal and cell shape changes in tubulogenesis. However, studies of other systems suggested a role for cell death in creating a luminal cavity, and early studies of thyroid follicle cells and blood vessel endothelial cells noted a possible role for cytoplasmic vesicles in lumen formation.

Tubulogenesis processes appeared to have little in common mechanistically. This view began to change over the past few years as modern cell biological tools were applied to cell culture systems in which the cellular events in tube formation could be carefully analyzed. Results from a number of systems, like the MDCK and endothelial cell culture systems converged on a critical role for apical membrane biogenesis and vesicle fusion in creating a lumen. During this same period, studies of tube growth and maturation in several invertebrate and vertebrate organs, including respiratory and renal organs, also directed attention to morphological and molecular events at the apical surface.

The concept of a common pathway of tubulogenesis began to emerge. Despite the wide variety of tubulogenesis mechanisms, emerging descriptions of the cellular and molecular events of tubulogenesis in a number of diverse systems have converged on apical membrane

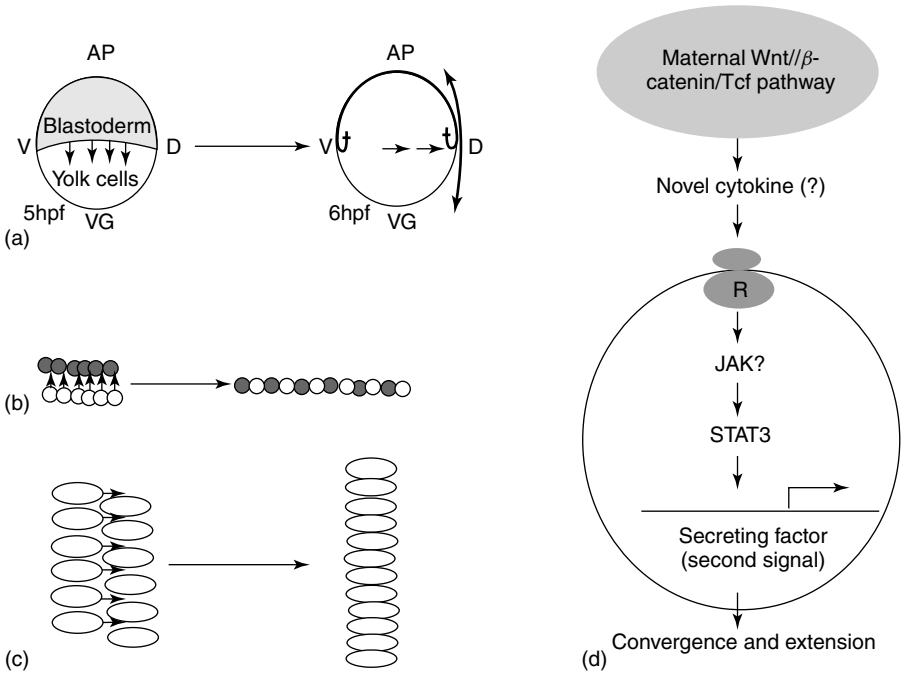

Fig. 7 Gastrulation movements in zebrafish. (a) During the early zebrafish development, four cell movements occur. First, blastomeres move down the surface of the centrally located yolk cell from the animal pole toward the vegetal pole (green arrows), a process called *epiboly*. Shortly after 6 h of development, 3 additional cell movements begin. Internalization (blue arrows) results in the formation of a localized thickening of cells known as the *germ ring*. Convergence of cells (red arrows) toward the future dorsal side of the embryo creates the embryonic shield, and extension (orange arrows) causes an elongation of the embryonic shield. (b) Epiboly is a radial intercalation process; deeper cells move up and insert themselves between more superficial neighbors, which leads to the spreading and thinning of the tissue. (c) Cells intercalate along the D/V axis during the dorsal convergence of lateral mesendodermal (LME) cells. (d) An activation of STAT3 on the dorsal side is regulated by the maternal Wnt/-catenin pathway and requires a Tcf transcription factor. An unidentified upstream molecule, possibly a cytokine or growth factor capable of activating STAT3 in early embryogenesis, is proposed to be one of the targets of the maternal Wnt/-catenin pathway. No JAK has yet been shown to be involved in STAT3 activation. The JAK/STAT signal may regulate the expression of a second signal molecule in prechordal mesendodermal (PCME) cells. The LME cells possibly sense the local gradient of the second signal and converge dorsally. AP, animal pole; VG, vegetal pole; V, ventral; D, dorsal; hpf, hr postfertilization. Hou et al. (2002). (See color plate p. xxiv.)

biogenesis, secretion, and other events at the apical surface as critical steps in tube formation and growth. Although the full process is not understood for any system, and the genes and molecules involved are just beginning to be characterized, the available data allow us to piece together a general mechanistic framework for tubulogenesis (see Fig. 8).

One of the surprising findings of early descriptions of tubular organ development is that, like chick neural tube formation, the tubes comprising some organs are not all created in the same way. The

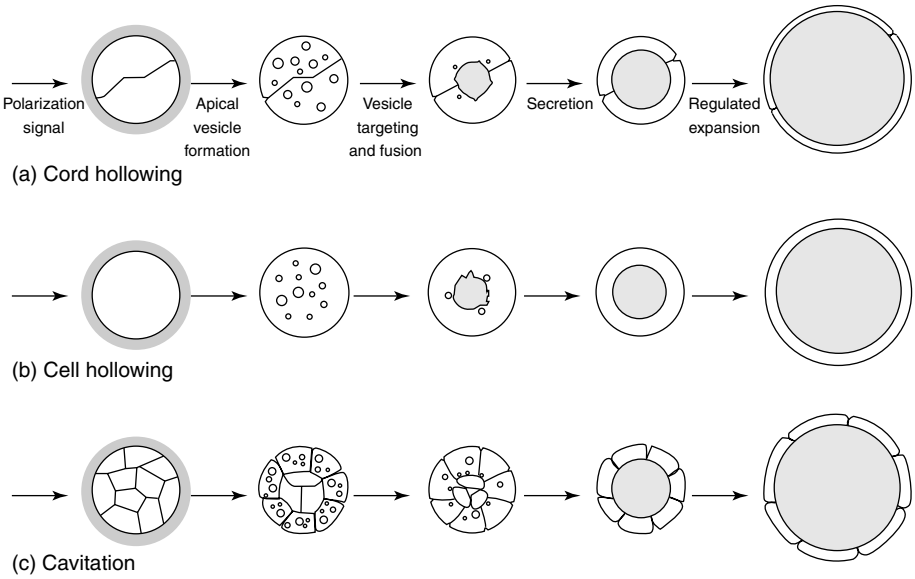

Fig. 8 A common pathway of tubulogenesis. Cells about to undergo (a) cord hollowing, (b) cell hollowing, or (c) cavitation follow a similar series of cellular events to create tubes. After receiving a polarization signal (green shading) that sets apicobasal polarity, the cells establish a basal surface (green) and generate vesicles carrying apical membrane antigens (red circles). The vesicles are targeted to the prospective apical region, where they fuse with the existing membrane or each other to form a lumen. Continued vesicle fusion and apical secretion expands the lumen. Expansion is a regulated process that continues until it is inhibited by a tube-size sensor set to trigger at a specific value for each tube. The sensor feeds into apical membrane biogenesis and secretory controls, as well as mechanisms for building apical structural support. During cavitation, interior cells fail to receive the polarizing signal and are left within the developing lumen and subsequently eliminated by cell death. Lubarsky and Krasnow (2003). (See color plate p. xxi.)

best-known example is the blood vessel development, where some vessels arise by the cord hollowing mechanism described above and others form by budding from the walls of existing vessels or by extensive remodeling of existing vessels. Similarly, in the mammalian kidney, the collecting ducts and distal tubules arise by sprouting from existing tubes or sacs, whereas proximal tubules arise from condensations of mesenchymal cells that assemble into tubes *de novo* and connect to the existing network. In the *Drosophila* tracheal system too, different mechanisms are employed at different stages of branching to generate the tubular network. If each of these mechanisms of tubulogenesis is not fundamentally different but represents a distinct variation on the general tubulogenesis process, then it is easier to envision how such tubular networks evolved: by the emergence of new variants of the tubulogenesis pathway that create tubes of specific sizes or shapes or different functional characteristics within a network. And, if it were easy to generate such variants during evolution, this would help explain how differences arose among related species in the tubulogenesis processes that form the neural tube and other organs such as the heart.

Although we are beginning to pinpoint some of the critical cellular and molecular events of tubulogenesis and can formulate a speculative general model for the process, we expect rapid progress in this area from a large number of systems using a variety of experimental approaches. A field of tube morphogenesis is emerging that not only seeks to answer the fundamental questions of how tubes are made and shaped but also how these processes go awry in human diseases associated with tube structural defects. Further investigations of the model systems and exploration of human diseases will continue to provide insights into the molecules and mechanisms of tube morphogenesis. These may in turn suggest ways to repair tubular defects or engineer better tubes.

3 Cell Differentiation

As the field of cell differentiation has generated vast literature, a model of cell differentiation, the role of pRb (retinoblastoma protein) in differentiation will be considered here.

Cell differentiation is characterized by permanent withdrawal from the cell cycle. Evidence for a role of pRb in cell differentiation came from Rb1 knockout mice ($Rb^{-/-}$), which die *in utero*. The correlation between death of $Rb^{-/-}$ mice and tissue-specific peak levels of pRb in normal mice suggested an essential role of pRb in development.

The expression levels of pRb protein in early mouse development are highest in brain, blood-forming cells of the liver, megakaryocytes, and skeletal muscle. Loss of pRb interferes with differentiation and can reactivate the cell cycle even in terminally differentiated cells.

The active role of pRb in differentiation has been studied in a number of cell lines inducible for differentiation. In each instance, an early event in differentiation was the dephosphorylation of pRb, which correlated with cell cycle arrest in G_0/G_1, a prerequisite to enter the differentiation pathway.

During differentiation of muscle cells, pRb accumulates in the nucleus and forms complexes with muscle-forming transcription factors such as MyoD and myogenin, thus preventing pRb rephosphorylation and locking the cell in the differentiated state. However, inactivation of pRb reverses the differentiated phenotype and allows cells to reenter the cell cycle.

The role of the E2F transcription factors is important in exiting the cell cycle and entering the differentiation pathway; these transcription factors are targets of pRb during growth suppression. When HL60 cells are induced to differentiate the ratio of pRb/p130 to the total E2F pool, shifted to a surplus of pRb/p130, resulting in complete sequestration of all E2Fs. In addition to E2F-1 to -3, E2F-4 was shown to bind pRb under these circumstances suggesting that pRb levels might be critical for the decision to enter S-phase or undergo differentiation. Overexpression of E2F-1 blocked terminal differentiation of megakaryocytes resulting in cell accumulation and apoptosis.

The role of p107 in differentiation seems to be more controversial than that of pRb. During myocyte differentiation, the expression levels usually go down, but in $pRb^{-/-}$ myoblasts, p107 is able to bind MyoD and compensate for myogenic differentiation. However, p107 is unable to hold the differentiated phenotype, since upon serum stimulation, it is downregulated and the cells reenter the cell cycle, an effect not observed in $pRb^{+/+}$ cells.

4
The Cell Cycle and Development

The relationship between the cell cycle and development is a topic that is of great interest to developmental cell biologists. Since the classic cell cycle, G1, S, G2, M was worked out in the 1950s it has been intensively studied by cell biologists. Also, it has long been known that the cell cycle of embryos undergoing cleavage is not classical, but is an abbreviated cycle consisting of S alternating with M. This embryonic (before gastrulation) cell cycle, using maternal gene products and not providing time (G1) for cell growth, results in cleavage of the zygote into an ever-increasing number of blastomeres of progressively decreasing size, that is, multicellularity is achieved at the expense of cell size. The midblastula transition of early *Xenopus* development has been used to study the conversion of S/M to G1/S/G2/S.

In a recent review of a book (Bock et al. (2001)) on the cell cycle and development, much of the current knowledge in developmental control of the cell cycle on many levels and in a variety of organisms is summarized, and is the prime source of the following information. The symposium on which the book is based is concerned with exploring the interplay between the cell cycle and the developmental programs employed by various organisms.

How and why does the ''standard'' cell cycle change in developing organisms, and what are the mechanisms that bring about these changes? How and why is the progression through the major cell cycle phases affected? What influences a cell's decision to stop proliferating and to differentiate at a certain point in the developmental program, and how is differentiation achieved?

Cell cycle alteration and regulation during development is a fundamental topic in considering the relationship between the cell cycle and development.

Xenopus oocytes and early embryos are excellent systems for studying the relationship between the cell cycle and development. Oocyte maturation is a hormonally triggered developmental switch that involves precise controls on M-phase entry and exit. *Xenopus* embryos bracketing the midblastula transition provide a developing system for the study of the sequential establishment of cell cycle checkpoints and the connection of signaling pathways to regulation of cell cycle progression(Fig. 9).

Further work in the *Xenopus* system should continue to provide fundamental insights into the interface between cell cycle control and developmental decisions.

Studying mechanisms that drive cell cycle transitions in developing *Xenopus* have included paying special attention to *Xenopus* oocyte maturation, as well as to the development of checkpoint control of the cell cycle. Studying the effect of DNA damage in the early embryo reveals that DNA damage has no effect on early *Xenopus* embryos, but when damaged embryos reach the onset of gastrulation, rapid and synchronous apoptosis occurs, implying that the DNA damage checkpoint is activated at this stage. Studies of early mouse embryos have focused on cell cycle transitions undergone during the first mitotic cleavages.

The degree to which the cell cycle can be altered to serve the changing needs of the developing organism is provided by studying *Drosophila* development. During *Drosophila* embryonic development, cell cycle progression is mediated exclusively by cell-type-specific transcriptional enhancers. Such control makes sense during this developmental phase, since

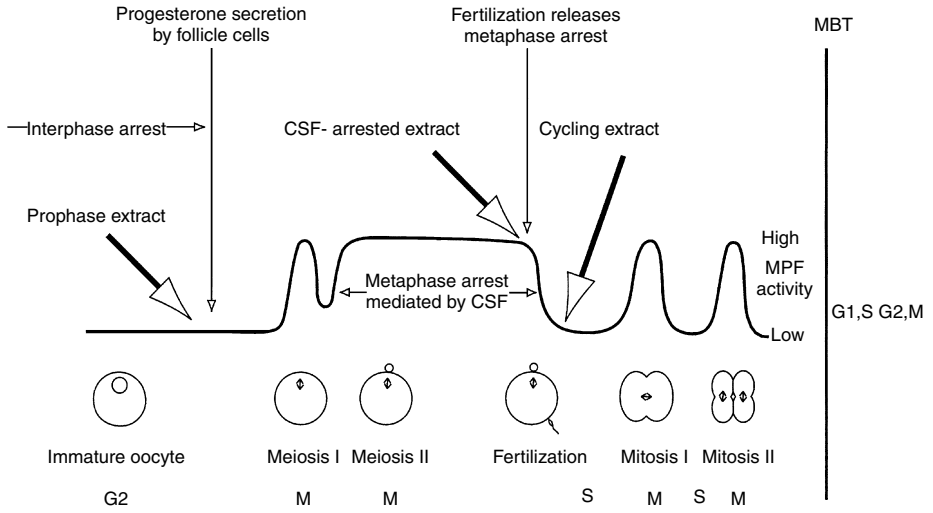

Fig. 9 Schematic diagram of early *Xenopus* development. The figure shows relative levels of MPF (cyclinB/Cdc2) activity from the beginning of oocyte maturation until after fertilization. Maller et al. (2001).

Drosophila embryonic cells undergo minimal growth between divisions. There is no need for cells to pause for growth following mitosis; the key event during this developmental phase is patterning, and this is quickly and effectively accomplished by allowing exclusive control of cell proliferation by pattern-inducing transcriptional enhancers. As development progresses to the larval phase, the developmental objective changes, and so too does the nature of the cell cycle. The major objective of *Drosophila* larval tissues is cell growth rather than cell proliferation; larval cells undergo repeated rounds of endoreplication, an effect that may be designed to increase the total gene dosage in a given cell in an effort to support drastically increased cell size. In such cells, the cell cycle is controlled by nutrition; adequate nutrition triggers further rounds of DNA synthesis. In the undifferentiated larval imaginal cells, a combination of the two regulatory schemes mentioned above is observed. Imaginal disk cells in the developing larva must undergo both growth and patterning, and exhibit a ''classical'' G1/S/G2/M cell cycle, with a growth-sensitive cell cycle checkpoint at the G1/S boundary and a patterning checkpoint at the G2/M boundary. The developmental program thereby neatly adjusts the cell cycle to promote patterning without growth, growth without patterning, or growth and patterning simultaneously, as each is required for proper development.

Closely related to cell cycle alteration during development is the topic of differentiation and cessation of proliferation. Eventually, most developing cells stop proliferating and specialize. What is the mechanism by which the transition from proliferation to specialization is achieved and timed? The asymmetrical nature of cell divisions has been considered, in the context of *Drosophila* neural progenitor cells, with focus on the protein interactions involved as well as the mechanisms of asymmetric cell division. Timing of differentiation has also been considered in

Drosophila with special attention paid to the global versus cell-intrinsic nature of the timing mechanisms, and in *C. elegans*, focusing on the tight control of postembryonic cell division by temporal regulation genes of the heterochronic gene pathway.

The timing of cell cycle exit and proliferation in mammalian oligodendrocyte development is a process notable for the autonomous control displayed by individual cells *in vitro*. Sister oligodendrocyte precursor cells plated in individual microwells differentiate at approximately the same time. Moreover, the differentiation mechanism does not count cell divisions as illustrated by the observation that at lower temperature conditions, cells divide more slowly, but differentiate after fewer divisions. It therefore appears that oligodendrocyte differentiation is controlled by a cell-intrinsic timing mechanism.

Regarding the molecular underpinnings of the cellular mechanisms involved, asymmetric spindle positioning in the developing *C. elegans* embryo has been studied in the context of the forces exerted by the cell to induce such asymmetry.

5 Organogenesis

A recent paper (Arnone (2002)) considers the current status of our knowledge about the regulation of organogenesis. Differentiated groups of cells make up tissues and organs. Each organ has a characteristic structure and function, which emerges during the development of the embryo, and thus needs to be studied on an individual basis. Many tissue-specific factors that regulate transcription and induce differentiation have been identified, but how they fit into the general phenomenon of organogenesis remains unclear. It is also likely that additional important factors have not yet been identified. Future research into the genesis of various tissues and organs will be designed to identify these as-yet-unknown factors and to integrate these and the currently known factors into a general understanding of organogenesis. Practical applications of this knowledge will include repairing and/or replacement of patients' compromised organs, probably beginning with the patient's own stem cells.

It has been proposed that the relative affinities of organ-identity transcription factors for different target sites control the timing of expression of downstream genes during development. How are organs, typically composed of many different cell types spatially and functionally organized into a unit, initiated and formed during embryonic development? The processes of morphogenetic pattern formation that underlie the construction of organs always have the same initial event – specification of the part of the embryo where organogenesis will begin. The process of organogenesis has a prerequisite step: the specification of spatially defined regulatory domains that promote the differentiation programs. This commonplace mechanism enables the recognition and definition of regulatory fields as discrete territories of specific gene activities.

A model for the regulation of organogenesis has been proposed, as shown in Fig. 10.

Selector genes control the formation and identity of the various fields. Field-specific genes are a special class of selector genes that have the unique property of directing the formation of complex, specialized structures such as organs; they are usually necessary and often sufficient to establish organ identity. Examples of such organ-identity genes include

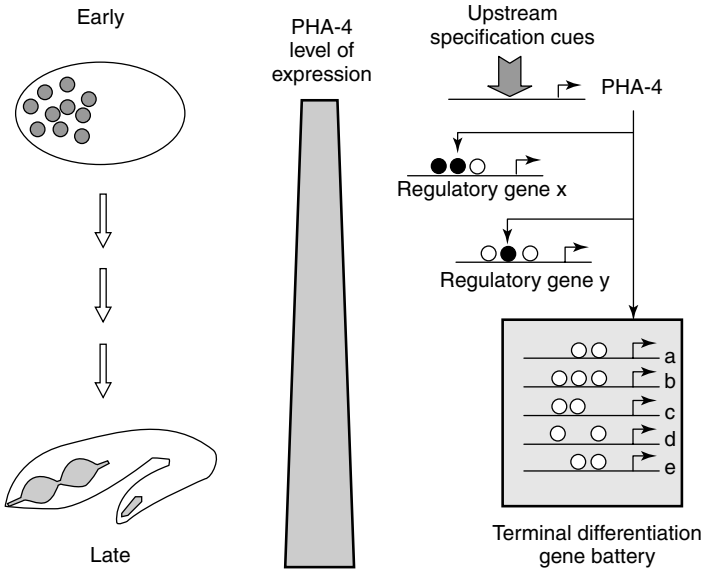

Fig. 10 The product of the organ-identity gene *pha-4* controls pharynx formation in the *C. elegans* embryo. PHA-4 protein (shown in orange or red on the left side of the figure) is present in the nuclei of essentially all pharyngeal cells throughout development. PHA-4 expression levels (shaded wedge at the center) increase as development progresses. PHA-4 directly regulates most pharyngeal genes (red arrows). Both early-acting regulatory genes (*x* and *y*) and late-acting structural genes involved in terminal differentiation (a to e in gray box) are shown on the right side of the figure, bearing one or more PHA-4-binding sites in their cis-regulatory elements (horizontal black lines). In the model proposed, the relative affinities of PHA-4 protein for different targets (open and closed circles for low- and high-affinity sites respectively) modulate the timing of pharyngeal gene expression throughout the genetic regulatory network. Arnone (2002). (See color plate p. xxvi.)

Pax6/eyeless which is required for eye formation in *Drosophila* imaginal discs and *Pit1*, which, together with *Gata2*, controls pituitary differentiation. How do organ-identity genes execute their function?

A frequently observed developmental feature offers a clue: organ-identity genes often act both early and late in the process of organogenesis. The same transcriptional regulators that are necessary for the initial specification of a certain organ are also required for the transcription of structural genes involved in terminal differentiation. What mechanisms allow a differentiation gene battery to be activated only at the end of the process of specification when the genes that regulate them are expressed and active earlier?

In experimental terms, one must find both early and late targets of these genes and study their cis-regulatory systems. Such an approach to study pharynx formation in the nematode *C. elegans* was taken. The precursors of the pharynx are generated by two distinct genetic pathways that eventually converge on the *pha-4* locus. *Pha-4* loss-of-function mutants fail to produce pharynx cells. Conversely,

ectopic *pha-4* expression produces excess pharyngeal cells. *Pha-4* encodes a *FoxA* homolog that is expressed in all pharyngeal precursor cells at the time they are restricted to a pharyngeal fate. In sum, *pha-4* specifies pharyngeal organ identity in *C. elegans*. What are the mechanisms that act downstream of this gene to mediate pharyngeal organogenesis?

By incubating labeled complementary DNA derived from *C. elegans* embryos with microarrays comprised of probes representing 11,917 *C. elegans* genes, and characterizing the resulting candidate pharyngeal genes, it was found that 76 genes are selectively expressed in the pharynx. The cis-regulatory regions of eight of these genes were characterized by reporter-construct analysis using green fluorescent protein. Pharynx-specific expression of all the eight reporter constructs was found to be dependent on the integrity of putative PHA-4 binding sites present in varying copy number within their cis-regulatory elements. Mutations affecting one or more of these binding sites eliminated, dramatically reduced, or delayed the pharynx-specific reporter gene expression.

Expression of these pharynx-specific genes is probably the result of *pha-4*-specific activity. The use of a *pha-4* temperature-sensitive mutant demonstrated that *pha-4* activity was also required for pharynx-specific expression of reporter constructs. Shifting from permissive to restrictive temperature (or *vice versa*) resulted in reduction (or reactivation) of pharynx-specific gene expression. PHA-4 was able to bind *in vitro* to the putative PHA-4 binding elements found in these pharynx-specific promoters.

It was observed that PHA-4 binds to the various target sites with different affinities, suggesting a possible regulatory mechanism for controlling the temporal onset of expression of the genes bearing these target sites. Their results offer a very simple model for regulation of pharynx formation – the product of the organ-identity gene *pha-4* directly activates most of the genes downstream of the process of initial specification, and the relative affinities of PHA-4 for different target sites modulate the timing of gene expression throughout the regulatory network. Consistent with this hypothesis, PHA-4 is expressed at low levels in the early stages of *C. elegans* development, and its expression progressively increases thereafter.

5.1 Chalones

The topic of chalones was recently (Gamer et al. (2003)) put into a historical and contemporary context. This topic relates to the phenomenon of organogenesis. How does an organ ascertain that it has reached the appropriate size during development? It was proposed that the existence of soluble factors produced locally by an organ as it develops act to limit further growth of that organ once it reaches its appropriate size. These soluble factors were named chalones; however, interest in them faded away when these factors could not be purified.

Recently, the discovery of a new TGF-like molecule, Gdf8 (also called *myostatin*), that is expressed in all skeletal muscles, was reported; it was found that, after birth, mice developed from *Gdf8* null embryos exhibited a dramatic and widespread increase in skeletal muscle mass with twice the amount of muscle. It has been shown that GDF8, secreted by differentiating myoblasts, inhibits the proliferation of neighboring muscle precursor cells, arresting them in the G1 phase of the cell cycle. The ability of GDF8 to keep muscle size in check revived the idea of chalones.

Wu et al. demonstrated that during embryonic neurogenesis, GDF11, a TGF-like molecule that is almost identical to GDF8, may act as a chalone in the nervous system. Unlike *Gdf8, Gdf11* expression is not specific for a single tissue. They reasoned that GDF11 could be the inhibitory signal they had been searching for that controlled the number of neurons that differentiate from neural progenitors during embryogenesis. Using mouse olfactory epithelium (OE) as a model, it was shown that Gdf11 and its receptors are expressed by neurons and neuronal progenitors in the OE and that exogenous GDF11 inhibits OE neurogenesis *in vitro* by inducing *p27Kip1* expression and reversible cell cycle arrest in neuronal progenitors. They also demonstrated that mice lacking a functional *Gdf11* gene have increased numbers of neuronal progenitors and neurons in the OE, while mice lacking follistatin, a GDF11 antagonist, show the reverse effect, a dramatic decrease in OE neurogenesis. They conclude that the negative autoregulatory action of GDF11 is strikingly similar to the action of GDF8 in skeletal muscle, demonstrating that similar strategies are used to establish and maintain proper cell number in nervous tissue and muscle, as seen in Fig. 11.

Experiments involving GDF8 and GDF11 demonstrate that molecules fitting some of the requirements of Bullough's chalones are produced and act locally. How this local activity relates to the regulation of organ size still remains a mystery. It seems that chalones are back with a vengeance.

6 Stem Cells

A stem cell is a cell that undergoes mitotic cell division to give rise to the same type

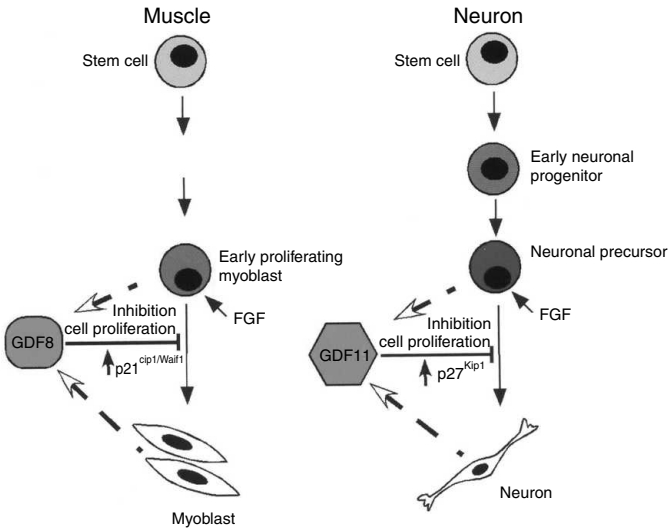

Fig. 11 Regulation of tissue size by GDFs. During neurogenesis and myogenesis, the negative autoregulatory action of GDFs on cell proliferation sets a limit on the number of mature neurons and muscle cells, maintaining control of organ size. Wu et al. (2003). (See color plate p. xxii.)

of cell. At some point, stem cells leave the pool of mitotically dividing cells to begin a process of cell differentiation. Stem cells are, in effect, an embryonic population of cells, continually producing cells that can undergo further development within an adult organism. The path of differentiation that a stem cell descendant enters depends on the molecular milieu in which it resides, for example, erythrocytes, granulocytes, neutrophils, platelets, and lymphocytes share a common precursor cell – the pluripotential hematopoietic stem cell.

The AGM region consists of the aorta, gonads, and mesonephros region. It is the domain, near the aorta, where, in fishes, mammals, and frogs, the definitive hematopoietic cells are formed. These mesodermal regions of the day-11 mouse embryo are where pluripotential hematopoietic stem cells (HSC) and CFU-s (colony-forming unit of the spleen) cells can be found. These blood cell precursors will colonize the liver and constitute both the fetal and adult circulatory system. Around the time of birth, stem cells from the liver populate the bone marrow, which then becomes the major site of blood formation throughout adult life.

The term pluripotent describes a cell that is capable of giving rise to several of the cell types of an organism, for example, the pluripotent stem cells of the bone marrow give rise to all classes of blood cells and neural crest cells can differentiate into different cell types, such as cholinergic neurons and adrenergic neurons, depending on their location. The pluripotent epidermal stem cell is a stem cell whose offsprings become epidermis, sebaceous gland, or hair shaft; the pluripotential hematopoietic stem cell is the common precursor cell shared by erythrocytes, basophils, eosinophils, mast cells, monocytes, tissue macrophages, osteoclasts, neutrophils, platelets, and T- and B-lymphocytes; and the pluripotent neural stem cell (NSC) is a stem cell whose offspring become neural and glial cells. The stratum germinativum, the innermost layer of the epidermis, contains mitotic stem cells required for the continual replenishment of the epidermis.

Hemangioblasts are the common precursor cells shared by blood vessels and blood cells; true blood cell stem cells of the chick embryo are derived from the splanchnopleure and formed within nodes of mesoderm that line the mesentery and the major blood vessels. Hematopoietic stem cells are those cells that generate the different types of blood cells. Hematopoietic inductive environments (HIMs) are regions where blood-forming cells undergo determination; the developmental pathway taken by the descendants of a pluripotential stem cell depends on which growth factors it is exposed to, which, in turn, is determined by the stromal cells to which it is exposed. Stem cells in the spleen become predominantly erythroid while those in the bone marrow become predominantly granulocytic. Stromal cells of the bone marrow create HIMs by their ability to bind hematopoietic growth factors; without these growth factors, the stem cells die.

Lineage-restricted stem cells are cells that can produce only one type of cell in addition to renewing itself, for example, the BFU-E (burst-forming unit, erythroid) is a lineage-restricted stem cell; it can form only one cell type, CFU-E (colony-forming unit, erythroid), in addition to itself. CFC-Meg is a lineage-restricted stem cell, derived from the myeloid precursor cell; it gives rise to megakaryocytes, which, in turn, give rise to platelets. The CFU-GM lineage-restricted stem cell, derived

from a CFU-M, L, gives rise to the granulocyte precursor cell and the monocyte. Osteoclasts, cells that have the ability to break down already-formed bone, play an important role in bone remodeling. Osteoclasts come from the CFU-GM, the same stem cell as macrophages and granulocytes; the growth factor interleukin 6 (IL-6) stimulates the production of osteoclasts; the production of IL-6 is inhibited by estrogen and testosterone. Osteoprotegerin, osteoclastogenesis inhibitory factor, is a member of the TNF receptor superfamily; together with its ligand, it regulates conversion of a macrophage stem cell into an osteoclast.

CFU-M, L is the colony-forming unit of the myeloid and lymphoid cells, a pluripotential hematopoietic stem cell, from which both the CFU-S and lymphocytes are derived. This cell gives rise to the CFU-S (blood cells) and the CFU-L (lymphocytes). CFU-S, a pluripotential hematopoietic stem cell, is capable of forming erythrocytes, granulocytes, and platelets. However, the immediate progeny of the CFU-S are lineage-restricted stem cells, for example, the BFU-E (burst-forming unit, erythroid) can form only one cell type in addition to itself.

The myeloid precursor cell is the pluripotent stem cell, which gives rise to three kinds of lineage-restricted stem cells: (1) CFU-GM, (2) CFC-Meg, and (3) BFU-E. The lymphoid precursor cell is the pluripotent stem cell, which gives rise to pre-T and pre-B cells; these cells, in turn, give rise to T-cells and B-cells, respectively; the terminally differentiated cells of this lineage are activated T-cells and plasma cells, respectively.

Embryonic germ (EG) cells are primordial germ cell (PGC)-derived cells; these pluripotent embryonic stem cells (ESCs) may be produced in culture by treating PGCs with stem cell factor, leukemia inhibition factor, and basic FGF2. Stem cell factor (SCF) is a paracrine protein that promotes cell division in numerous stem cell populations; mice lacking SCF or its receptor (c-Kit protein) are sterile (no germ cells), white (no pigment cells), anemic (no red blood cells), and immunodeficient (no lymphocytes). Fibroblast growth factor, a family of protein growth factors, first identified as mitogens for fibroblasts in tissue culture, stimulates proliferation of many cell types, inhibits differentiation of various types of stem cells, and acts as inductive signals in embryonic development. EG cells have the potential to differentiate into all the cell types of the body; they are often considered to be embryonic stem cells, ignoring the distinctiveness of their origin.

Embryonic stem cells are stem cells derived from the embryo, for example, derived from normal mouse inner mass cells cultured *in vitro*. Use of these cells to make chimeras allows investigators to introduce an engineered gene with a known mutation into ES cells and then to breed mice that have the same mutation in all their cells.

Cord blood is blood obtained from the umbilical cord at the time of delivery, a rich source of stem cells.

The oogonium (plural, oogonia) is a type of female germ cell that functions as a stem cell until it begins to undergo cell differentiation and becomes an oocyte. In humans, all oogonia have differentiated into primary oocytes before the birth of a female; however, in frogs oogonia persist throughout reproductive life as a stem cell population, multiply and produce eggs for the next breeding system. Spermatogonia are male germ cells that act as stem cells and may undergo meiosis and cell differentiation to become spermatozoa (gametes). Spermatogonia

are spermatogenic (sperm producing) cells. Various types of spermatogonia are recognized in humans, that is, A_1, A_2, A_3, A_4, intermediate, and B. It is thought that each of the A types are stem cells, capable of renewal; intermediate spermatogonia are committed to becoming spermatozoa and divide to form type B spermatogonia; type B spermatogonia are the precursors of spermatocytes. In 1840, Albrecht Koelliker realized that sperm from the male and ova from the female were cells; he earned his doctorate with work that traced the development of spermatozoa from stem cells to their release from the testes.

Nurse cells of the *Drosophila* ovary are produced by stem cells undergoing four mitotic divisions (one of the resulting 16 cells, per stem cell, becomes the oocyte; the others become nurse cells). The nurse cells produce large quantities of proteins and RNAs that are exported into the egg through cytoplasmic bridges. Bicoid mRNA is made by nurse cells located next to the anterior end of the developing oocyte and is transferred from them into the egg.

A meristem is a part of a plant characterized by dividing cells; these regions of plants contain stem cell populations that produce cells, some of which go on to differentiate into plant tissues and some of which constantly renew the stem cell population. Generally, two varieties are found: (1) apical meristems, found at the tips of plant parts, for example, at the growing ends of roots and shoots and (2) lateral meristems, found on the sides of plants, for example, vascular cambium and cork cambium are lateral meristems found under the bark of tree trunks. The primary root of a flowering plant has three meristematic regions: the procambium, the ground meristem, and the protoderm, which give rise to primary tissues.

Primary tissues are plant tissues produced directly by the activity of apical meristems; the procambium gives rise to the primary xylem, vascular cambium (a lateral meristem), and primary phloem; the ground meristem gives rise to the pericycle, endodermis, and cortex; and the protoderm gives rise to the epidermis.

In the procedure known as therapeutic cloning, nuclear material from a donor somatic cell is transferred into an enucleated egg cell and ESCs are harvested from the resulting blastocyst; if the ESCs can be coaxed to differentiate into functioning tissues, the new cells may be introduced into the donor to regenerate diseased tissue and even organs. An objective of therapeutic cloning is to derive immunologically compatible embryonic stem cells.

Recently, citing new data, that is, the first genome-wide transcript analysis of ESCs, HSCs, and NSCs produced by transcriptional profiling of purified stem cell populations it was pointed out that the new data sets begin to establish the nature of ''stemness.'' Burns and Zon (2002) suggest an alternative to the Till and McCulloch stochastic model of 1961, the multilineage priming model of May and Ever, a more modern model for stem cell fate that suggests that stem cells express a low level of lineage affiliated genes, which are amplified or repressed upon differentiation, that is, it may be the specific combination of genes rather than individual genes that endow the unique properties of stem cells, priming them to accept specific environmental cues.

It was noted that, despite these recent advances, the intrinsic program induced by environmental cues has not been molecularly described and that further analysis is clearly required to ascertain the relevance of the identified core stem cell genes, suggesting that the functionally

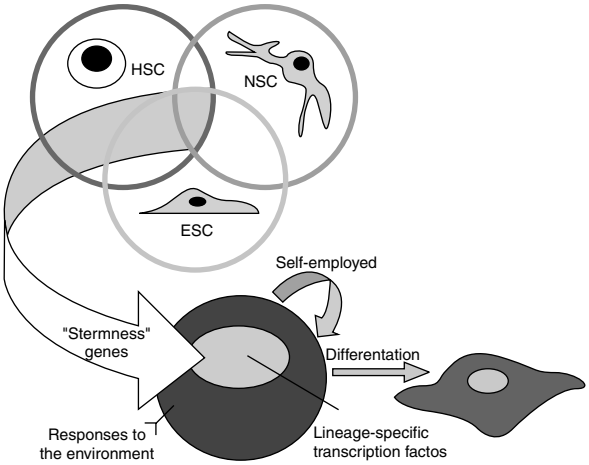

Fig. 12 Theoretically, all stem cells (ESC, HSC, and NSC) may share a core set of ''stemness'' genes that enable both self renewal and differentiation. These internal programs may be regulated by environmental cues. Each individual stem cell also expresses a set of individual lineage-specific genes. The specific combination of common and lineage-specific transcripts and the biased distribution of internal factors may lead to stem cell asymmetric division. Burns and Zon (2002).

important genes will likely be uncovered by comparing stem cells in different lineages and species. See Fig. 12.

7 Cloning

A clone may be defined as (1) a population of cells derived from a single cell by mitosis or (2) a group of organisms produced by asexual reproduction, for example, vegetative propagation in plants, parthenogenesis in animals, nuclear transfer techniques involving the transfer of somatic cell nuclei of identical genetic constitution into enucleated eggs. These definitions notwithstanding, cloning may be applied at the molecular and nuclear levels, as well as at the cellular and organismal levels.

In molecular cloning (gene cloning), there is amplification (by the polymerase chain reaction) of single genes to a chemically useful quantity. The polymerase chain reaction (PCR) is a highly efficient, *in vitro*, enzymatic method of cloning (making many identical copies of) specific pieces of DNA.

Positional gene cloning is a method used to find genes that are involved in normal human development and whose mutations cause congenital developmental malformations. Pedigree analysis highlights a region of the genome where a particular mutant gene is thought to reside; by making a DNA map of that area, one may find a region of DNA that differs between people who have the mutation and people who lack it; then by sequencing that region of the genome, the gene can be located, for example, the discovery of the human *Aniridia* gene. Such candidate gene mapping was used to study Waardenburg sydrome type 2, that is, pedigree

analysis was used to determine that Waardenburg sydrome type 2 is caused by a mutation in a gene on the small arm of chromosome 3, between bands 12.3 and 14.4; using a probe made from the mouse microphthalmia gene, it was found that a human homolog (*MITF*) of the mouse microphthalmia gene mapped to exactly the same region as Waardenburg syndrome type 2.

In the procedure known as knockout or targeted gene knockout, the targeted disruption of function in a cloned gene, the gene is usually introduced back into the organism in such a way as to replace a normal gene copy, by homologous recombination, in order to analyze the effect of the mutation. Interestingly, in many cases knocking out a normal gene has had no effect at all, even when the gene was thought to be essential. Two genes exhibit genetic redundancy when the absence of the function of one gene causes little or no effect because a second gene can operate in its place.

In cellular cloning, the founder cell gives rise to a particular group of cells, for example, a cell clone consists of all surviving descendants of a single cell, which is called the founder cell of the clone.

In therapeutic (or research) cloning, nuclear material from a donor somatic cell is transferred into an enucleated egg cell and ESCs are harvested from the resulting blastocyst. If the ESCs can be coaxed to differentiate into functioning tissues, the new cells might be introduced into the donor to regenerate diseased tissue and even organs. An objective of therapeutic cloning is to derive immunologically compatible embryonic stem cells. Reproductive cloning is cloning for reproductive purposes, that is, producing new organisms that are genetically identical to the donor of the nuclear material. Cloning, as applied to organisms, is the process (natural or artificial) of making several, genetically identical, independent organisms from a single initial organism.

In 1936, a ''somewhat fantastical'' experiment was suggested to transfer a nucleus from a differentiated cell into an enucleated egg. In 1952, Briggs and King developed the techniques for the frog (*Rana*); they transferred blastula stage cell nuclei into enucleated eggs and were able to obtain complete tadpoles. It was already shown that blastula cell nuclei were pluripotent, but what about nuclei from more advanced stages? In 1956, Briggs and King used somatic cell nuclei of tailbud-stage tadpoles (vs germ cell nuclei of tailbud-stage tadpoles); they demonstrated (1) an apparent decrease in nuclear potency and (2) apparently the decrease in nuclear potency was stable and tissue specific, as demonstrated by nuclear cloning, for example, endoderm nuclei appear to be good at making endoderm, but are restricted in making ectoderm and mesoderm. Progressive restriction of nuclear potency during development appeared to be the general rule. However, another possible explanation for limited potency would be chromosomal abnormalities. Gurdon, using the frog *Xenopus*, used intestinal endoderm of feeding tadpoles and seemed to demonstrate that these nuclei were totipotent. However, King criticized Gurdon's work; subsequently, Gurdon cultured epithelial cells from adult frog foot webbing and by serial transplantation was able to obtain tadpoles, but these died before feeding. These amphibian-cloning experiments suggested (1) that a general restriction of potency occurred with progressive development and (2) that the differentiated cell genome was remarkably potent. Debate persisted about the totipotency of

such nuclei, but there was little doubt that they were extremely pluripotent.

Dolly, the sheep, was the first mammal cloned from a cell of an adult animal. She was a result of an experiment to test the suitability of different sources of cells for nuclear transfer. She was derived from cells that had been taken from the udder of a six-year old Finn Dorset ewe and then cultured in the laboratory. Individual cells were then fused with unfertilized eggs from which the genetic material had been removed and 29 of these ''reconstructed eggs,'' each now with a nucleus from the adult animal, were then implanted in surrogate Blackface ewes. One gave rise to a live lamb, Dolly, some 148 days later. Other cloned lambs were derived in the same way from cells taken from embryonic and fetal tissue. Dolly was euthanized in February 2003 due to respiratory disease.

Somatic cell nuclear transfer (SCNT) is the technique whereby nuclear material from a donor somatic cell is transferred into an enucleated egg cell, generally, as part of a cloning technique.

Clonal analysis is a technique used in developmental biology as a form of fate mapping, in which a single cell is labeled and the position and cell types of its progeny identified at a later stage. The *Minute* technique uses cells of *Drosophila* carrying a mutation in the *Minute* gene, which, therefore, grow more slowly than those in the wild type. By using flies heterozygous for the *Minute* mutation, clones can be made in which a mitotic recombination event has generated a marked cell that is normal because it has lost the *Minute* mutation, and so is wild type. This normal cell proliferates faster than the slower growing background *Minute* heterozygous cells, and thus large clones of the marked cells are produced.

Clonal restriction is found in insect compartments defined by clonal restriction lines, in which lines are not transgressed by cell clones generated after a certain stage of development.

Cystocytes are the cells of a clone of cells derived from the oogonium by meroistic oogenesis in insects; ring canals are connections between such clones.

Clonal selection theory is the concept that each animal first randomly generates a vast diversity of lymphocytes and then those cells that react against the foreign antigens that the animal actually encounters are specifically selected for action (form a clone).

Keywords

Diabetes Insipidus
Inherited or acquired disease characterized by polyuria and polydipsia.

Central Diabetes Insipidus
Diabetes insipidus caused by insufficient release of vasopressin from the neurohypophysis.

Nephrogenic Diabetes Insipidus
Diabetes insipidus caused by a resistance of the kidney toward the action of vasopressin.

Vasopressin
Nonapeptide synthesized in hypothalamic nuclei and released from the posterior pituitary. The main biological activity is conservation of water (via vasopressin V_2 receptors); therefore it is also termed *antidiuretic hormone* (ADH). Vasopressin also stimulates the contraction of vascular smooth muscle cells, glycogenolysis in liver cells (via vasopressin V_{1a} receptors), release of ACTH from the anterior pituitary (via vasopressin V_{1b} receptors), and secretion of the von Willebrand factor (via vasopressin V_2 receptors). In addition, vasopressin acts as a neurotransmitter in the central nervous system (via V_{1a} and V_{1b} receptors), regulating the adaptive and social behavior.

Oxytocin
Nonapeptide homologous to vasopressin, which is also produced in hypothalamic nuclei and released from the posterior pituitary. In the pregnant uterus, it potentiates the strength and frequency of smooth muscle contractions. After birth, stimulation of the nipple results in the release of oxytocin, which in turn causes contraction of myoepithelial cells of the mammary ducts and the ejection of milk.

G protein-coupled Receptors
Superfamily of membrane receptors, characterized by a common seven transmembrane-spanning configuration. Activation of the receptors by extracellular ligands causes stimulation of heterotrimeric G proteins.

Heterotrimeric G-proteins
Guanine nucleotide regulatory protein complexes composed of α and $\beta\gamma$ subunits. Upon activation by G protein-coupled receptors, they influence the activity of a large variety of effector molecules such as adenylyl cyclase, phospholipases, and ion channels.

Aquaporins
Integral membrane proteins with six transmembrane-spanning domains, allowing water to cross the plasma membrane rapidly. In man, 10 different aquaporins are known, of which seven are expressed in the renal tubular epithelium and the renal collecting duct. Aquaporins are also found in the epithelium and endothelium of brain, lung, and intestine.

The neurohypophyseal hormone vasopressin acts via three different G protein-coupled receptors. The main physiological response elicited by vasopressin is antidiuresis, which is mediated by vasopressin V_2 receptors in the kidney. Further responses, such as vasoconstriction and the release of the adrenocorticotropic hormone (ACTH), are mediated by vasopressin V_{1a} and vasopressin V_{1b} receptors respectively.

Diabetes insipidus is a hereditary or acquired disease characterized by polyuria and polydipsia. It is either caused by an insufficient release of vasopressin from the neurohypophysis (central diabetes insipidus) or by a resistance of the kidney toward the action of vasopressin (nephrogenic diabetes insipidus).

In the case of central diabetes insipidus, autosomal dominant and autosomal recessive modes of inheritance are known. In both traits, mutations in the vasopressin-neurophysin II gene (encodes the vasopressin precursor) are responsible for the disease. For congenital nephrogenic diabetes insipidus, three modes of inheritance are known: X-chromosomal recessive, autosomal recessive, and autosomal dominant. While the X-chromosomal trait is caused by mutations in the vasopressin V_2 receptor gene, the autosomal forms are due to mutations in the aquaporin-2 gene (encodes the vasopressin-regulated water channel).

Analysis of mutant vasopressin-neurophysin II, vasopressin V_2 receptor, and aquaporin-2 proteins revealed impaired protein transport as the most common cause of the disease. The transport defect is either caused by (1) retention of misfolded proteins in the endoplasmic reticulum or (2) misrouting of correctly folded proteins.

1 Vasopressin

1.1 Structure, Synthesis, and Release of Vasopressin

Vasopressin is a cyclic nonapeptide (Fig. 1a). Its amino acid sequence is highly conserved among mammals. Only swine and marsupials have a lysine residue at position 8 (Lys-vasopressin, LVP), whereas all other mammals display an arginine residue (Arg-vasopressin, AVP). AVP is highly homologous to oxytocin (Fig. 1b). The genes encoding AVP and oxytocin evolved from an anchestral gene by gene duplication. Both genes share a common gene structure and are only separated by 11 000 and 8 000 bps of noncoding DNA in rat and man respectively.

AVP and oxytocin are encoded as precursor proteins and are synthezised in magnocellular neurons of the supraoptic and paraventricular nuclei of the hypothalamus. The AVP precursor consists of a signal peptide, the hormone moiety (AVP), a carrier protein (neurophysin II), and a copeptin (Figs. 2 and 3). The oxytocin precursor comprises a signal peptide, the hormone moiety (oxytocin) and a carrier protein (neurophysin I). The neurophysins (neurophysin I and II) function not only as carrier proteins to protect the hormones from proteolytic degradation within the secretory vesicles but are also crucially involved in correct folding and processing of the precursor proteins. The function of the copeptin encoded by the *AVP-NPII* gene remains elusive.

In man, Arg-vasopressin (AVP) serum levels normally range from 2.5 to 5 pg mL^{-1}. The secretion of AVP is under the control of osmoreceptors in the hypothalamus and of baroreceptors located in the heart and the carotid artery. The osmoreceptors in the hypothalamus are activated by minute increases in the plasma osmolality (≥1%), which in turn stimulate the release of small quantities of AVP (changes of serum AVP are less than or equal to 1 pg mL^{-1}). Greater changes in plasma osmolality cause larger increases in plasma AVP of up to 10 pg mL^{-1}.

Relatively large changes in blood volume are necessary to stimulate AVP release

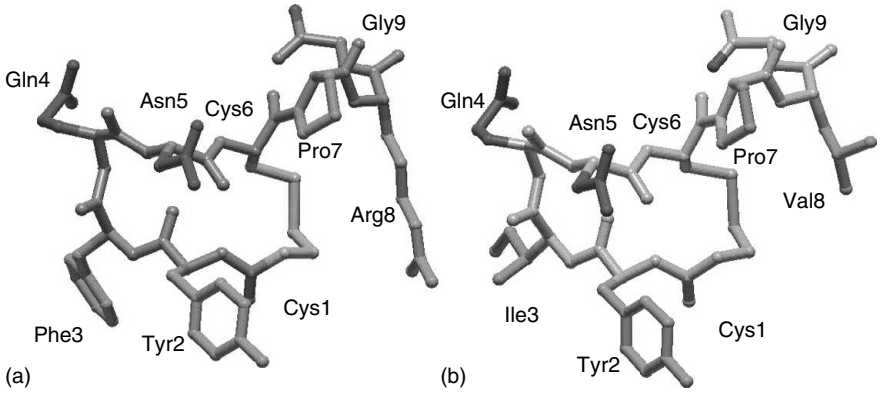

Fig. 1 Structure of cyclic nonapeptides vasopressin and oxytocin. Homology model of vasopressin (a) based on the crystal structure of oxytocin (b; Brookhaven 3D PDB: 1XY1). Amino acids are depicted in the three letter code. The numbers are the positions of amino acids within the molecules.

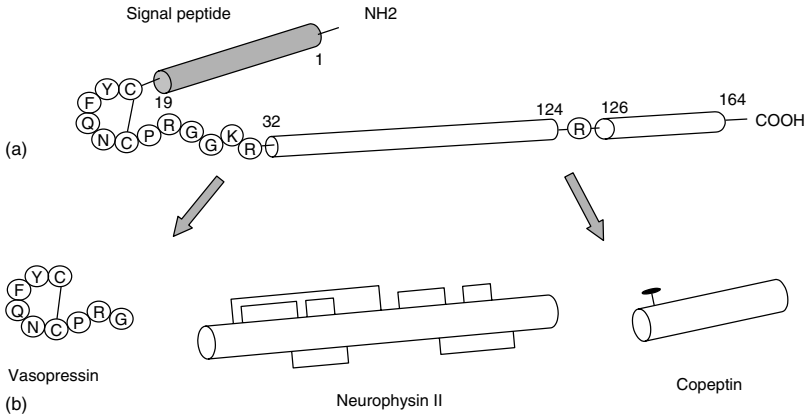

Fig. 2 Generation of vasopressin from the vasopressin-neurophysin II precursor protein. (a) Structure of the AVP-NPII precursor protein; (b) mature vasopressin, neurophysin II, and copeptin. Posttranslational modifications shown are intramolecular disulfide bonds in the vasopressin and neurophysin II moiety, glycosylation of the copeptin.

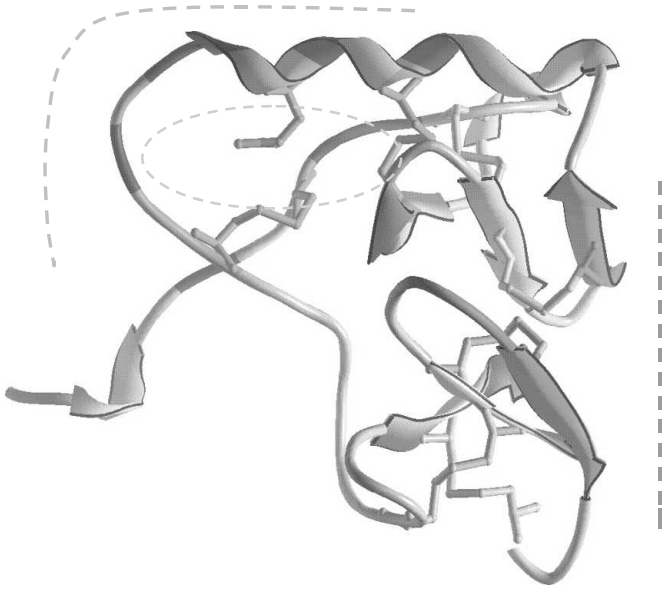

Fig. 3 Crystal structure of bovine neurophysin II (Brookhaven 3D PDB: 2BN2). *Blue* – amino acids interacting with vasopressin, *blue circle* – docking site of vasopressin, *yellow* – disulfide bonds, *green* – amino acids, involved in the dimerization of NPII, *green dotted line* – contact site of NP II dimers, *red* – amino acids involved in the tetramerization of NPII, *red dotted line* – contact site of the tetramer. Dimerization of two NPII molecules has been experimentally verified. Tetramerization was found in the crystal structure, but its physiological significance has not yet been determined. (See color plate p. xxvii.)

via baroreceptors. While a decrease in the blood volume of less than 10% is insufficient to stimulate AVP secretion, the acute loss of more than 10% dramatically increases AVP secretion: Plasma levels of AVP can reach 100 pg mL^{-1} if the blood loss exceeds 20 to 30%. While antidiuresis is maximally stimulated at about 10 pg mL^{-1} AVP, vascular effects such as vasoconstriction are observed only at higher AVP levels (10–100 pg mL^{-1}).

2 Vasopressin Receptors

2.1 Structure and Expression of Vasopressin Receptors

AVP exerts its action via four distinct receptors belonging to two different types of membrane proteins. Three receptors, namely vasopressin V_{1a}, V_{1b}, and V_2 receptors (V_{1a}, V_{1b}, and V_2 receptors), belong to the superfamily of G protein-coupled receptors. These proteins share a common topology with an extracellular N terminus, an intracellular C terminus and seven transmembrane domains (Fig. 4). The G protein-coupled vasopressin receptors are encoded by three different genes and show a distinct pattern of tissue expression (Table 1). The binding site for AVP is formed by the transmembrane domains and the first and second extracellular loops. The docking of AVP elicits a conformational change, which in turn leads to the activation of heterotrimeric G proteins. The activated G proteins in turn can modulate the function of effector molecules, such as adenylyl cyclase, phospholipase Cβ, or diverse ion channels. The receptor-stimulated physiological response depends on the cellular environment and the nature of the activated G proteins (see Sect. 2.2).

The fourth vasopressin receptor, the vasopressin-activated calcium-mobilizing receptor (VCAM-1), is a single transmembrane receptor comprising about 780 amino acids. It has been identified in man, rat, and rabbit. VCAM-1 does not possess any homology to the G protein-coupled vasopressin receptors. It belongs to a new

Tab. 1 Synoposis of the chromosomal localization, tissue expression, and activated signal cascades of vasopressin receptors.

Type of receptor	*Chromosomal localization*	*Exon number*	*Signaling*	*Site of expression*
V_{1a}	12q14-q15	2	G_q, G_i, $G_{12/13}$	Vessels (smooth muscle cells) Liver (hepatocytes) Kidney (interstitial cells)
V_{1b}	1q32	2	G_q, ($G_{12/13}$)	Adenohypophysis (basophilic cells) Adrenal gland (chromaffine cells) Pancreas (β cells)
V_2	Xq28	3	G_s	Kidney (principal cells) Vessels (endothelium)
VACM-1	11q22-q23	20	$Ca^{2+}\uparrow$, G-protein-independent	Renal collecting duct Endothelial cells

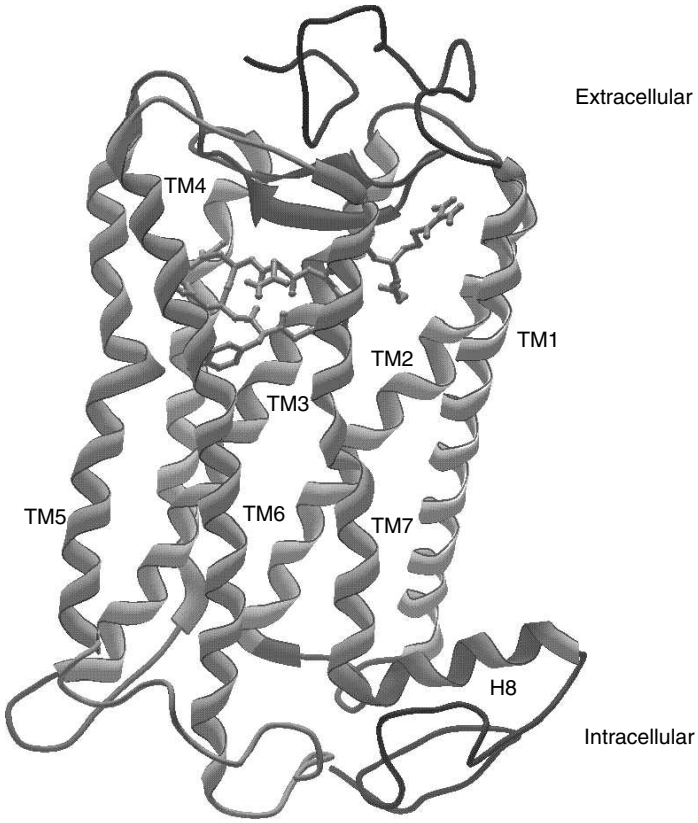

Fig. 4 Homology model of the ligand-bound vasopressin V_2 receptor based on the 3D model of bovine rhodopsin (Brookhaven 3D PDB: 1L9H). Seven transmembrane helices are labeled TM1 to TM7. For clarity, the transmembrane helices in the front are in cyan and the transmembrane helices at the back are gray. *Dark blue lines* – N and C tail, *red lines* – 1st extracellular/intracellular loop, *magenta lines* – 2nd extracellular/intracellular loop, *green lines* – 3rd extracellular/intracellular loop. *Yellow* – synthetic agonist DDAVP. A short helix (H8) is found between TM7 and the C tail. (See color plate p. xxviii.)

family of peptide receptors, designated as cullins. VACM-1 shows homology with cullin-5 of *Caenorhabditis elegans*, a protein involved in the control of the cell cycle, and when mutated, contributes to tumor progression. Binding of AVP leads to an increase in calcium by a yet unknown mechanism.

In the rat, a further AVP-sensitive receptor, the dual angiotensin II/AVP (AngII/AVP) receptor, has been described. Up to now, the existence of this receptor in any other species has not been reported.

2.2 Signal Transduction of G protein-coupled Vasopressin Receptors

The V_{1a} receptor mainly activates G proteins of the $G_{q/11}$ and the $G_{12/13}$

family. Depending on the cell cycle, V_{1a} receptors also have the ability to activate G proteins of the G_i family. The V_{1b} receptor activates G proteins of the $G_{q/11}$ family and the V_2 receptor stimulates the G protein G_s.

Activation of G proteins of the G_q family leads to a stimulation of the phospholipase Cβ, which catalyzes the formation of inositoltriphosphate (IP_3) and diacylglycerol (DAG). IP_3 and DAG function as second messengers. DAG activates multiple isoforms of protein kinase C, which in turn phosphorylate a great number of diverse proteins at serine and threonine residues, thereby regulating the functional activity of the proteins. IP_3 mediates the release of calcium from the smooth endoplasmic reticulum via the IP_3 receptor. The increase of intracellular calcium stimulates the release of ACTH in basophilic cells (via the V_{1b} receptor) of the anterior pituitary and mediates the constriction of vascular smooth muscle cells (via the V_{1a} receptor, Fig. 5). In addition, the stimulation of $G_{12/13}$ has a synergistical action on smooth muscle cell contraction, resulting in a prolonged vascular smooth muscle contraction.

In the case of the V_2 receptor, the activation of G_s leads to the stimulation of the adenylyl cyclase, resulting in the generation of the second messenger cyclic adenosine monophosphate (cAMP). High levels of cAMP stimulate the cAMP-dependent protein kinase (PKA), which in turn phosphorylates several proteins, among

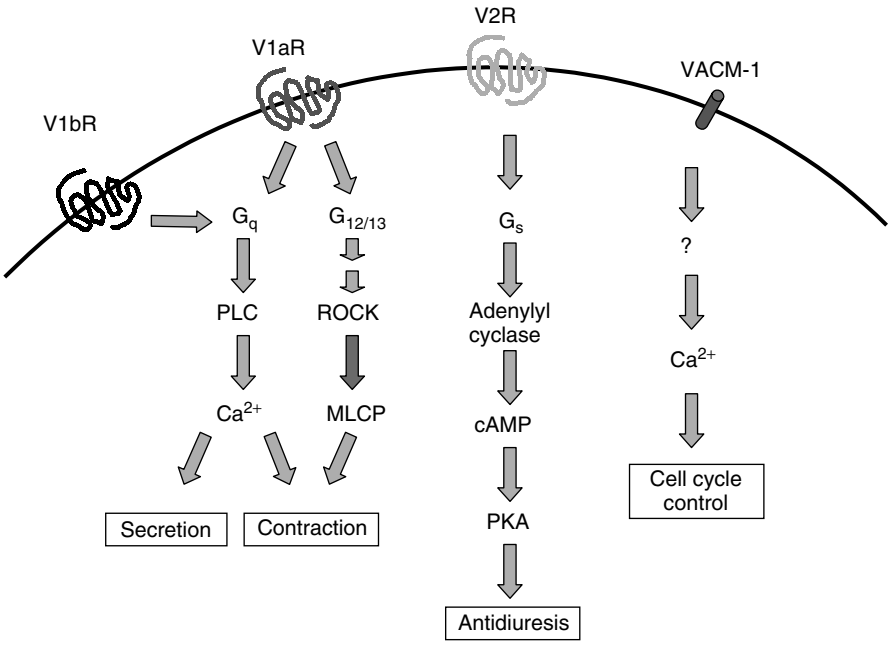

Fig. 5 Synopsis of signaling cascades activated by vasopressin receptors. Shown here are the three heptahelical G protein-coupled vasopressin receptors ($V_{1a}R$, $V_{1b}R$, and V_2R) and the single transmembrane spanning vasopressin-sensitive calcium-mobilizing receptor (VACM-1). *Green arrows* – activation, *red arrow* – inhibition. (See color plate p. xxix.)

others the AVP-sensitive water channel aquaporin-2 (AQP2) and the small G protein Rho A. The cAMP/PKA-mediated signaling events finally result in the translocation of submembranously stored AQP2-harboring vesicles into the apical plasma membrane (Fig. 5; see Sect. 3.3 below).

3 Aquaporins

3.1 Requirements for Water Channel Proteins

In the collecting duct of the kidney, the apical membrane must maintain large chemical and osmotic gradients and therefore be effectively impermeable to ions and most other small molecules. This is achieved by high concentrations of glycosphingolipids and sphingomyelin in the outer leaflet of the epithelial lipid bilayer. Expression and regulated insertion of specific water-permeable transmembrane channels, that is, aquaporins (AQP), represent an elegant way for the organism to regulate the water permeability of these critical barrier interfaces. In response to AVP, the abundance of aquaporins in the apical membrane of principal cells increases, and the epithelia can become about 50-fold more water-permeable. AQPs have little importance in slow water transport, which occurs across plasma membranes for housekeeping functions such as volume regulation. Rather, they are important for rapid vectorial water transport in response to osmotic gradients created by continuous flow or active salt pumping. Consequently, water-transporting proteins are expressed not only in renal collecting duct but also in other fluid-transporting epithelia and endothelia.

3.2 Structural Features Responsible for Water Selectivity

The members of the water channel protein family are homotetramers containing four independent water channels. Aquaporins are characterized by two tandem repeats consisting each of three transmembrane helices and a short loop (Fig. 6). The latter bears the signature motif Asn-Pro-Ala (NPA). The atomic structure of various AQP family members suggests that the NPA motif is crucial for water selectivity. Meeting with their positive ends in the middle of the membrane, the dipoles of the two short loops force the water molecules passing in single file to reorient (Fig. 7). The reorientation disrupts the hydrogen bonds between the two central water molecules. This mechanism is assumed to inhibit Grotthuss proton diffusion involving the chemical exchange of hydrogen nuclei between hydrogen-bonded water molecules in the channel. As revealed by molecular dynamic simulation, another highly conserved residue, a positively charged amino acid Arg187 (Arg-195 in AQP1), may be even more important for the exclusion of protons and ions from the water pathway. Pointing into a channel that is so narrow that water molecules cannot pass each other, its positive charge electrostatically prevents any cation (including H_3O^+) from entering the channel (Fig. 7).

3.3 The Main Aquaporins in Kidney

The archetypal member of the aquaporin family, AQP1, is highly abundant in the proximal tubule, the thin descending limb of Henle and the descending vasa recta. It is exclusively expressed in segments of the nephron that are constitutively and highly

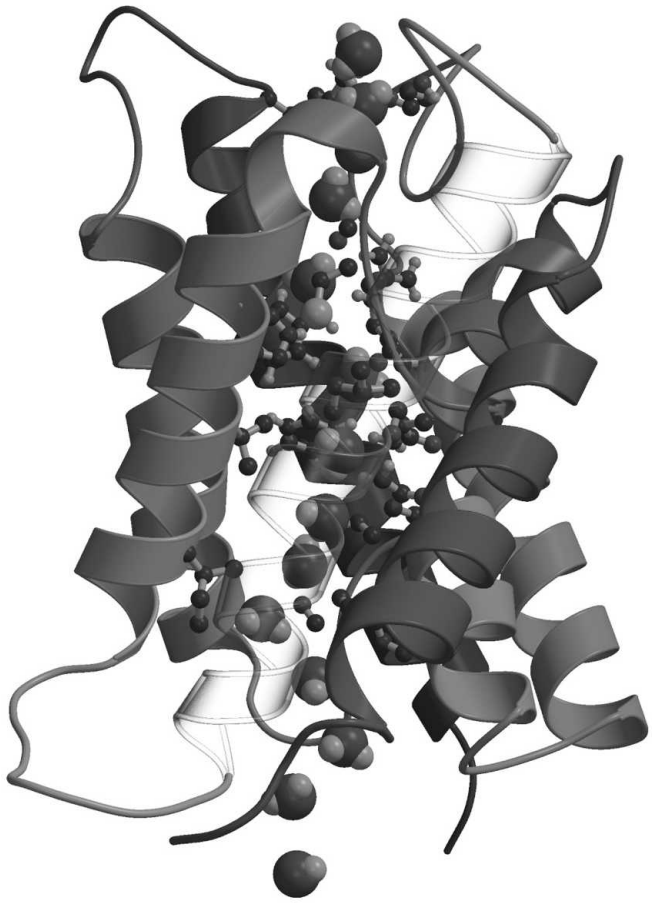

Fig. 6 The structure of human AQP1. The water channel protein is responsible for the efficient water transport in kidney proximal tubule. The pore is formed by six transmembrane helices. Two of the connecting loops fold back into the protein forming two short helices (*blue*). Water molecules (*red* – oxygen, *white* – hydrogen atoms) cross the channel in a single-file configuration. The pore is so narrow that water molecules cannot pass each other. The sequence-related water-transporting protein in the kidney collecting duct, AQP2, is expected to have a similar atomic structure of the water pathway. The figure was kindly provided by B. de Groot (modified from de Groot, B.L., Grubmuller, H. (2001) Water permeation across biological membranes: mechanism and dynamics of aquaporin-1 and GlpF, *Science* **294**, 2353–2357). (See color plate p. xxxi.)

water permeable. The protein facilitates water movement across both the apical and basolateral membranes. AQP3 and AQP4, in contrast, are found only in the basolateral but not in the apical membrane of collecting duct principal cells. Using a sodium concentration gradient as a driving force, water enters these cells via AQP2

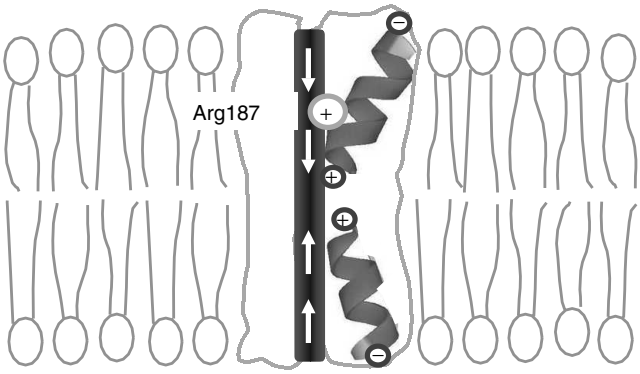

Fig. 7 The selectivity filter of AQP2. The water pathway is shown in blue. Water molecules cross the channel in an oriented fashion. In the middle of the membrane, the water dipoles (*white arrows*) undergo a rotation. It is governed by partial charges from the dipoles of the short helices. Thus, the structure of the central pore region is designed to disrupt the hydrogen bonds between neighboring water molecules. Thereby, protons are prevented from crossing the channel by the Grotthuss mechanism (by structural diffusion along the water wire). The positively charged Arg187 is a barrier for cation movement (including H_3O^+). (See color plate p. xxiii.)

and crosses to the interstitial fluid through AQP3 and AQP4. AQP2 abundance in the apical plasma membrane is hormonally regulated, thus determining the water permeability of the collecting duct. Long- and short-term regulation mechanisms can be distinguished. Long-term AVP treatment increases the expression level of AQP2 and AQP3 in parallel. Short-term regulation is restricted to AQP2. It is accomplished by the AQP2 shuttle (see Sect. 3.4). AQP4 appears not be regulated or at least not as markedly as AQP2 and AQP3.

3.4 The AQP2 Shuttle

Acute regulation of body water balance requires mechanisms that are much faster than the augmentation of protein expression levels. The rapid increase in collecting duct water permeability, that is, the fast increase of AQP2 abundance in the plasma membrane, results from exocytosis of AQP2-containing intracellular vesicles (Fig. 8). In the first step, AVP binds to the V_2 receptor expressed on the basolateral membrane of renal principal cells. Stimulation of the V_2 receptor leads to a rise of cAMP and cytoplasmic Ca^{2+}. The subsequent phosphorylation of AQP2 initiates a long-range AQP2 redistribution from vesicles distributed throughout the cell to the apical plasma membrane. The prominent terminal web of actin filaments in the apical part of principal cells appear to be involved in the AQP2 translocation, since disruption of microfilaments with cytochalasins stimulates the plasma membrane insertion. The final step is the exocytotic insertion of AQP2 into the plasma membrane resulting in an increase in the osmotic water permeability (Fig. 8). Trafficking to the plasma membrane is impaired by most mutations in AQP2, even though some of the mutants will act as functional water channels (see Sect. 4.2).

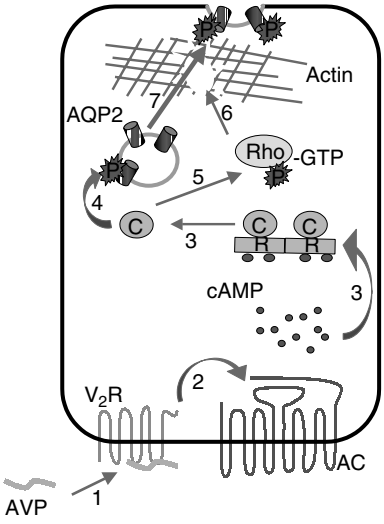

Fig. 8 The AQP2 shuttle. In a first step (1), the antidiuretic hormone AVP binds to the V_2 receptor (V_2R) expressed in principal cells, which are the main epithelial cell type of the medullary collecting duct. Stimulation of the V_2 receptor on the basolateral surface of principal cells activates the adenylyl cyclase (2). The increased cyclic AMP levels, in turn, activate PKA (3). Substrates of PKA are AQP2 (4) and Rho (5), which are phosphorylated. The phosphorylation of Rho favors the depolymerization of the F-actin cytoskeleton (6) and allows translocation of AQP2-bearing vesicles to the cell membrane (7). Subsequent fusion of the vesicles with the plasma membrane increases the membrane abundance of AQP2, thereby facilitating osmotic water transport.

4
Diabetes Insipidus

Diabetes insipidus is an acquired or inherited disorder of water homeostasis, characterized by polyuria and excessive thirst. It is either caused by an insufficient release of AVP from the posterior pituitary (central diabetes insipidus) or by a resistance of the kidney to the action of AVP (nephrogenic diabetes insipidus). The urinary volume exceeds 50 mL kg^{-1} bodyweight in 24 h. The specific gravity and the osmolality of the urine are less than 1010 g L^{-1} and 300 mosmol L^{-1} respectively. In severe cases, the volume exceeds 200 mL kg^{-1} bodyweight in 24 h, and the urinary osmolality is less than 100 mosmol L^{-1}. In these cases, the patients life is ruled by frequent drinking and by micturition every 30 to 60 min both day and night. The large amounts of urine may cause a dilation of the urinary tract resulting in hydronephrosis and renal insufficiency. Infants are under particular threat, since insufficient fluid intake results in severe dehydration with plasma osmolality and plasma sodium exceeding 320 mosmol L^{-1} (>10% increase in osmolality) and 160 mmol L^{-1} respectively. Recurrent episodes of dehydration result in a failure to thrive and may cause mental retardation. Both sequelae can be completely prevented by sufficient fluid intake.

4.1
Central Diabetes Insipidus

Central diabetes insipidus is characterized by an inadequate or no release of AVP from the posterior pituitary. Frequent causes of central diabetes inspidus are brain tumors, pituitary surgery, and severe head injuries, which disrupt the axonal projections of the AVP-producing magnocellular neurons. Depending on the neuronal lesion, diabetes is transient (regeneration of the magnocellular neurons) or persistent (degeneration of neurons). In idiopathic central diabetes insipidus, which typically manifests in childhood and early adult life, the cause is unknown.

Congenital forms of central diabetes insipidus are rare. A comprehensive list of known mutations in the *AVP-NPII* gene is presented on the web (http://www.medicine.mcgill.ca/nephros/avp_npii.html). In most of the cases, an autosomal dominant mode of inheritance is found. So far, only three cases of autosomal recessive central diabetes insipidus have been reported.

4.1.1 Autosomal Dominant Central Diabetes Insipidus

The congenital forms of central diabetes insipidus show an autosomal dominant mode of inheritance. The penetrance is almost 100%. While newborns and infants rarely present with symptoms, polyuria and polydipsia typically become apparent in children older than one year (the onset can vary between 1 and 30 years of age).

Genetic analysis of the autosomal dominant central diabetes insipidus have revealed about 40 different mutations within the *AVP-NPII* gene. The majority of mutations (33 of 40) are found in the region encoding the neurophysin II moiety. Five mutations lead to an altered amino acid sequence of the signal peptide, and one mutation causes an amino acid substitution within the AVP moiety (Fig. 9). The great majority of AVP-NPII mutants is characterized by amino acid substitutions in the neurophysin II moiety. This may be explained by the fact that neurophysin II is not only a carrier protein for AVP but also of essential importance for the correct folding and processing of AVP in the precursor.

The molecular mechanisms underlying the dominant mode of inheritance are still not fully understood. The delayed onset of the disease argues against a dominant negative effect of the mutant AVP-NPII precursor. It is more likely that secondary events elicited by mutant AVP-NPII proteins contribute to the pathomechanisms of the disease.

Several lines of evidence suggest that the mutant AVP-NPII precursor proteins have neuropathic or neurotoxic effects on AVP-producing magnocellular neurons. This is supported by neurohistological studies, in which selective

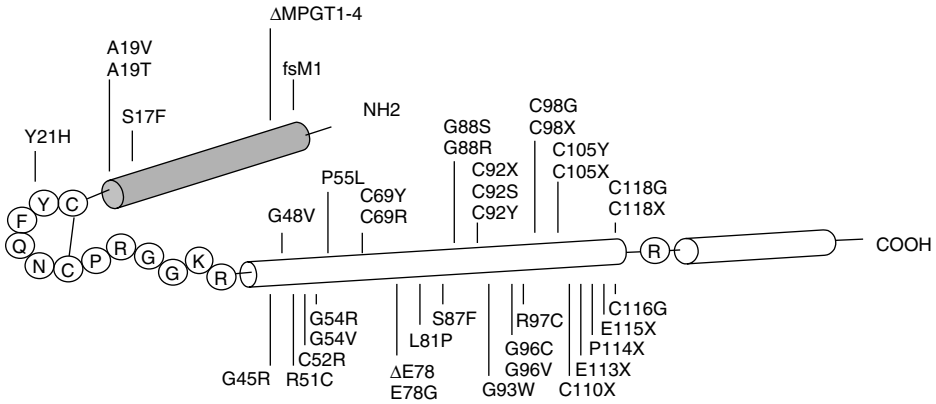

Fig. 9 Synopsis of AVP-NPII mutants responsible for autosomal dominant central diabetes insipidus. The mutants are depicted by the native amino acid (single letter code), the position in the AVP-NPII precursor protein, and the replacing amino acid. Δ – deletion of amino acids, fs – indicates nucleotide deletions causing a shift in the reading frame.

degeneration of AVP-producing but not of oxytocin-producing magnocellular neurons was found. *In vitro* analysis of differentiated neuronal cell lines that stably express mutant AVP-NPII precursor proteins demonstrated strong accumulation of AVP-NPII mutants within the ER and progressive cell death. The mechanisms involved in this process have not been explored in detail. However, recent studies on different secretory and membrane proteins suggest that ER accumulation causes cellular stress (unfolded protein response), which results in a number of effects including an increased synthesis of chaperones. The chaperones help to prevent the aggregation of misfolded proteins. If the native state of proteins is not achieved in subsequent folding cycles, degradation via the ubiquitin-proteasome system is initiated. However, this degradation can be impaired by several factors. For example, some mutant proteins have a high probability of forming aggregates spontaneously, as found for certain mutants of serine protease inhibitors. The formation of such aggregates prevents degradation of the misfolded proteins and is cytotoxic. Similarily, the excessive synthesis of a misfolded protein (like mutant rhodopsin in retinitis pigmentosa) also affects the cellular degradation machinery by unknown mechanisms.

4.1.2 Autosomal Recessive Central Diabetes Insipidus

So far, only three cases of congenital diabetes insipidus are known that show an autosomal recessive mode of inheritance. In all three cases, the patients presented with symptoms shortly after birth. In one case, a homozygous splice site mutation was identified. In a second case, a compound heterozygous mutation (a splice site and a nonsense mutation) in the *AVP-NPII* gene was found. In a third case, a homozygous *AVP-NPII* gene mutation encodes a mutant AVP, in which proline at residue 7 is replaced by leucine. This AVP mutant has a 30-fold lower affinity to the V_2 receptor than the native AVP. The parents, both heterozygous for the mutation, were reported to be healthy.

4.2 Nephrogenic Diabetes Insipidus

Nephrogenic diabetes insipidus is characterized by the resistance of the kidney to the action of AVP. Patients show polyuria and excessive thirst despite the presence of normal or elevated amounts of plasma AVP. Acquired forms of nephrogenic diabetes insipidus are much more frequent than inherited forms. The most common cause of nephrogenic diabetes insipidus is lithium, which is used for the treatment of bipolar manic-depressive illness. Polyuria can be found in up to 20% of patients receiving lithium. In most cases, polyuria is reversible after cessation of the therapy. However, in some patients, renal insufficiency can develop despite the cessation of lithium therapy. Patients presenting with impaired renal function as a result of long-term lithium therapy (creatinine serum levels >2.5 mg dL^{-1}) are under high risk of developing endstage renal failure.

Hypokalemia and hypercalcemia are metabolic disorders associated with less severe forms of nephrogenic diabetes insipidus, which are fully reversible when serum potassium or calcium values are normalized. In some instances, the antifungal amphotericin B or the microtubule inhibiting agents vincristine and colchicine can cause severe, but reversible nephrogenic diabetes insipidus.

Congenital diabetes insipidus is a rare disease with an estimated incidence of 8.8 per 1 000 000 males. Two genes have

been identified to be responsible for the disease: the genes encoding the G protein-coupled vasopressin V_2 receptor and the AVP-sensitive water channel AQP2. Inactivating mutations of the V_2 receptor show an X-linked mode of inheritance. Mutations of the AQP2 show an autosomal recessive or autosomal dominant trait. The onset and the symptoms are indistinguishable in X-linked and autosomal nephrogenic diabetes insipidus. Thus, an interruption of the signal cascade at the receptor or the effector level has identical consequences.

4.2.1 X-linked Nephrogenic Diabetes Insipidus

To date, more than 170 different mutations within the V_2 receptor gene that cause X-linked nephrogenic diabetes insipidus have been identified (refer to http://www.medicine.mcgill.ca/nephros/avpr2.html for a comprehensive list of reported mutations). The mutations are scattered throughout the coding region without evidence for a hypermutable region. About 50% of the mutations are missense mutations, leading to the exchange of a single amino acid. Roughly 10% are nonsense mutations resulting in a premature stop of the polypeptide synthesis. The remaining 40% of the mutations are deletions and insertions. Strikingly, most of the single amino acid substitutions (Fig. 10, green circles) are localized within the transmembrane regions. Further clusters of amino acid exchanges are found in the first extracellular loop and in the N- and C-terminal parts of the second extracellular loop.

In recent yeras, a large number of V_2 receptor mutants have been characterized for their functional defects. In general, three main defects have been identified: (1) a failure to reach the cell surface, (2) a decrease or loss of AVP-binding, and/or (3) a decrease or loss in G protein-coupling activity. The most common defect found in about two-thirds of the investigated mutants is an impaired transport to the cell surface, most likely mediated by the quality control system of the ER. The quality control system consists of a variety of different chaperones, which recognize and bind misfolded proteins. Thereby, the chaperons prevent the exit of misfolded proteins from the ER. If the native conformation cannot be formed, the misfolded proteins are finally degraded via the ubiquitin-proteasome system.

Amino acid substitutions leading to a defect in the binding of AVP are predominantly found in the first and second extracellular loop or at the junction of the transmembrane region and the extracellular space. This observation highlights the importance of the first and second extracellular loop of the V_2 receptor for the binding of AVP. In photoaffinity labeling experiments, threonine 103 and arginine 106 of the bovine V_2 receptor have been identified to be of crucial importance in ligand binding (Fig. 10, asterisks).

So far, only few V_2 receptor mutants have been identified that show a reduced ability or are unable to activate the G protein. In one mutant (in which arginine 137 at the junction of the second transmembrane domain, and the second intracellular loop is replaced by histidine; R137H), the loss of G protein-coupling could be assigned to a constitutive binding of the mutant receptor to the adapter protein β-arrestin.

4.2.2 Autosomal Recessive Nephrogenic Diabetes Insipidus

Genetic defects in the *AQP2* gene account for about 10% of congenital nephrogenic diabetes insipidus. The human *AQP2* gene

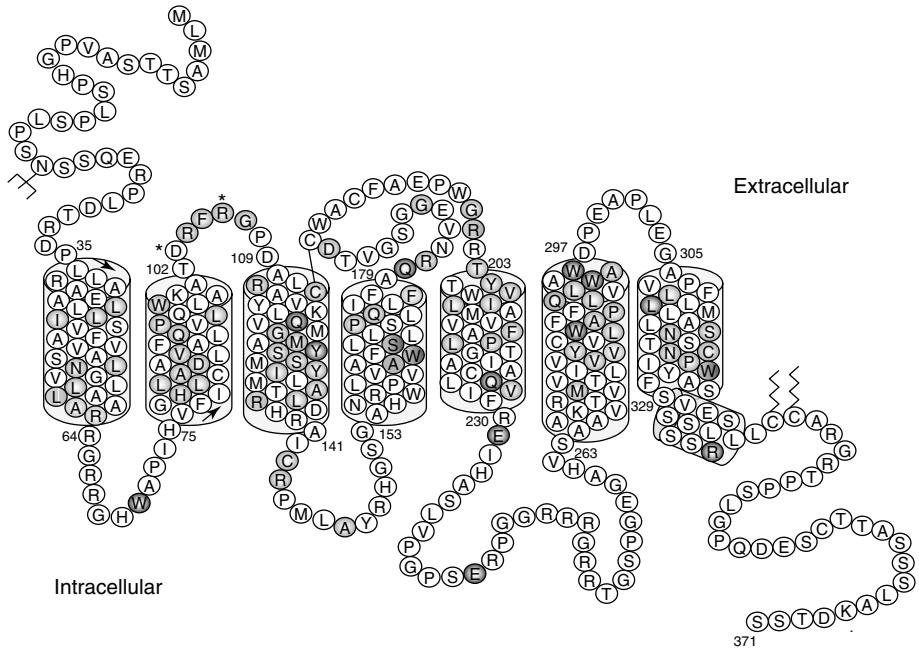

Fig. 10 Synopsis of vasopressin V_2 receptor mutants responsible for X-linked nephrogenic diabetes insipidus. Diagram of the human vasopressin V_2 receptor. Amino acids are shown in the single-letter code. The arrows in the first and second transmembrane domain show the succession of amino acids. *Stars* – indicate amino acids involved in ligand binding as demonstrated by photoaffinity labeling, *green circles* – missense mutations, *red circles* – nonsense mutations, *yellow circles* – in-frame deletions, *blue circle* – in-frame insertion, *yellow/green circles* – missense mutations and in-frame deletions found at this position, *red/green circles* – missense and nonsense mutations found at this position. Posttranslational modifications shown are glycosylation at asparagine 22, disulfide bonds between cysteine 112 and 192, and palmitoylation at cysteines 341 and 342. (See color plate p. xxx).

is located in the chromosome region 12q13 and has four exons and three introns. The majority of mutations show an autosomal recessive mode of inheritance, although autosomal dominant traits (see Sect. 4.2.3) are also possible. Most of the mutations are missense mutations, followed by frameshift mutations and seldomly occurring nonsense and splice site mutations. The mutations are located throughout the gene, affecting all transmembrane helices and connecting loops (Fig. 11). A comprehensive list of known *AQP-2* gene mutations is presented on the web (http://www.medicine.mcgill.ca/nephros/aqp2.html). Mutations found in the two loops bearing the signature motif NPA are likely to destroy the water-transporting part of the protein. For example, substitution of Arg187 for Cys disrupts the normal folding of the narrow constriction in the aqueous pore (Fig. 7). All mutant AQP2 proteins are retained in the ER (Fig. 12), although some of the mutants appear to be able to function as water channels. Thus, misrouting of mutant AQP2 proteins is the major cause of autosomal recessive nephrogenic diabetes insipidus.

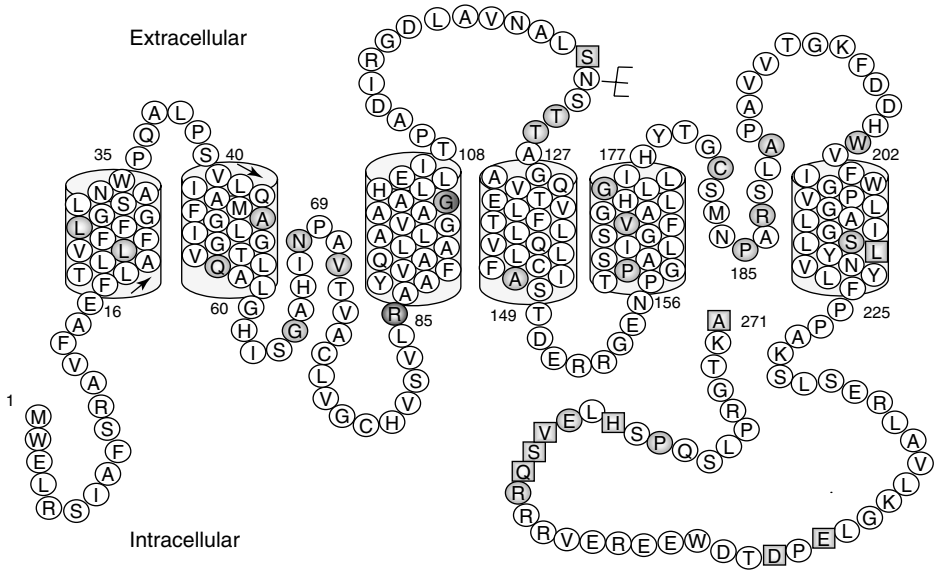

Fig. 11 Synopsis of mutant AQP2 water channel responsible for autosomal nephrogenic diabetes insipidus. Diagram of the human AQP2. Amino acids are shown in the single-letter code. The arrows in the first and second transmembrane domain show the succession of amino acids. Posttranslational modifications shown are glycosylation at asparagine 123. Mutations responsible for autosomal recessive diabetes insipidus: *Green circles* – missense mutations, *green squares* – nucleotide deletions causing a shift in the reading frame, *red circles* – nonsense mutations, *red/green circle* – missense and nonsense mutations found at this position. Mutations responsible for autosomal dominant nephrogenic diabetes insipidus: *blue circles* – missense mutations, *blue squares* – nucleotide deletions/insertions causing a shift in the reading frame. (See color plate p. xxix.)

4.2.3 Autosomal Dominant Nephrogenic Diabetes Insipidus

In some instances, nephrogenic diabetes insipidus shows autosomal dominant inheritance. In these cases, mutant AQP2 proteins inhibit the normal function of the coexpressed wild-type AQP2. Here, heterooligomerization between the mutant AQP2 and wild-type AQP2 occurs, which is not found for ''recessive'' AQP2 mutants. However, the heterotetramers do not show AVP-regulated translocation to the apical plasma membrane (dominant negative effect of mutant AQP2). The AQP2 mutant in dominant nephrogenic diabetes insipidus, E258K-AQP2, for example, is a functional water channel but it is retained in the Golgi complex. Misrouting to late endosomes/lysosomes or to the basolateral membrane may also occur (Fig. 12). All dominant forms of nephrogenic diabetes insipidus are due to mutations in the intracellular C terminus near the site that regulates exocytosis.

4.3 Treatment of Diabetes Insipidus

4.3.1 Treatment of Central Diabetes Insipidus

Central diabetes insipidus can be efficiently treated by the substitution of AVP. Since AVP also has vasopressor activity, the selective V_2

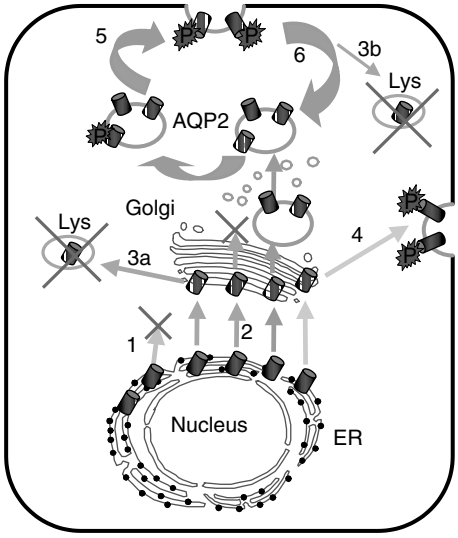

Fig. 12 Synopsis of routing defects of mutant AQP2 water channels. AQP2 mutants associated with autosomal recessive nephrogenic diabetes insipidus are retained within the endoplasmic reticulum (1, *ochre arrow*). Since the ''recessive'' AQP2 mutants exist as monomers, they do not affect the sorting of the wild-type AQP2. In contrast, AQP2 mutants associated with autosomal dominant nephrogenic diabetes insipidus affect sorting of the wild-type AQP2, since dominant AQP2 mutants and wild-type AQP2 form heterotetramers. So far, three different sorting defects of ''dominant-negative'' AQP2 mutants have been characterized: the mutant E258K-AQP2 is retained in the Golgi apparatus (2, *blue arrows*), the mutant ΔG727-AQP2 is constitutively transported to lysosomes (3a and 3b, *orange arrows*), and the mutant insA779-AQP2 undergoes PKA-dependent translocation to the basolateral plasma membrane (4, *cyan arrows*). Normal trafficking of AQP2 (*green arrows*) is not finished with its exocytic insertion (5) but also includes its endocytic retrieval (6). (See color plate p. xxvii.)

receptor agonist 1-deamino-8-D-arginine vasopressin (DDAVP, Minirin®) is preferred for hormonal replacement therapy. No serious adverse reactions of this treatment have been reported so far. Doses range from 5 to 60 µg each day.

4.3.2 Treatment of Nephrogenic Diabetes Insipidus

The most important treatment for nephrogenic diabetes insipidus is sufficient water intake adjusted to the increased urinary output. When recurrent episodes of hypernatremia are efficiently prevented, affected children develop normally. In the long run, control of the urinary output is of major importance. The large urinary volumes may lead to the dilation of the urinary system resulting in hydronephrosis and renal insufficiency. Currently, urinary volumes can be reduced by thiazide diuretics and/or inhibitors of the prostaglandin synthesis (inhibitors of cyclooxygenases – COXs). Thiazide diuretics cause a depletion of body sodium and a reduction in the glomerular filtration rate. As a consequence, the efficiency of thiazides in reducing urinary output is impaired by increased dietary sodium intake. Therefore, patients with congenital nephrogenic diabetes insipidus should receive a low sodium diet. Nutrition guidelines and patient-oriented information on nephrogenic diabetes insipidus are available on the web (http://www.ndif.org). Nonselective COX inhibitors reduce the glomerular filtration rate, thereby leading to a reduced urinary output. However, in patients with congestive heart failure, COX inhibitors impair renal function. In addition, nonselective COX inhibitors, like indomethacin, are associated with severe adverse drug reactions, such as gastrointestinal bleeding and headache. Such adverse reactions may not be seen with selective inhibitors of COX-2. Recent studies provided evidence that selective COX-2 inhibitors reduce urinary output in another congenital polyuric disease (antenatal Bartter/hyperprostaglandin E

syndrome) without evidence for serious adverse reactions. At present, it is not clear whether selective COX-2 inhibitors will be safe and efficient drugs for the treatment of nephrogenic diabetes insipidus.

5 Animal Models

5.1 Animal Models of Central Diabetes Insipidus

The Brattleboro rat shows central diabetes insipidus due to a spontaneous mutation in the *AVP-NPII* gene. Only rats homozygous for this mutation have diabetes insipidus, whereas rats heterozygous for the mutation are normal. Thus, Brattleboro rats show an autosomal recessive mode of inheritance. This model has been of greatest importance for the understanding of AVP-mediated antidiuresis and still is of value for the analysis of AVP-induced gene expression. However, the model does not contribute to the understanding of the cellular pathomechanisms underlying the autosomal dominant form of central diabetes insipidus.

5.2 Animal Models of Nephrogenic Diabetes Insipidus

To establish a model of X-linked nephrogenic diabetes insipidus, a premature stop mutation was introduced into codon 242 of the V_2 receptor gene (*E242X*). This mutation was originally identified in patients suffering from X-linked nephrogenic diabetes insipidus. The mutated gene encodes a V_2 receptor with only five instead of seven transmembrane domains. Male mice, hemizygous for the E242X mutant V_2 receptor are polyuric, but die within three weeks after birth. So far, treatment of these mice with thiazides and/or COX inhibitors did not improve survival. To establish a model of autosomal recessive nephrogenic diabetes insipidus, a missense mutation was introduced into codon 126 of the murine *AQP2* gene, which leads to the replacement of threonine 126 by methionine (T126M). This T126M mutant was identified in patients suffering from autosomal recessive nephrogenic diabetes insipidus. Mice homozygous for AQP2-T126M die within two weeks after birth.

6 Outlook

While central diabetes insipidus can be adequately treated by the administration of AVP or DDAVP, treatment of nephrogenic diabetes insipidus still poses a serious problem. Although urinary volume can be reduced by about one-third using thiazide diuretics or COX inhibitors, patients still pass large amounts of dilute urine. Frequent micturition, even throughout the night, affects the quality of life. The discovery of the genetic defects underlying nephrogenic diabetes insipidus allowed a firm diagnosis of the patients. However, this knowledge did not result in an improvement in the therapy.

An obstacle in improving the therapy of diabetes insipidus is a high degree of diversity in the underlying genotypes. There is no predominant mutation, as found, for example, in cystic fibrosis: Here, more than 60% of all patients encode the ΔF508 CFTR mutant, so that

research can focus on this particular mutation. Despite these obstacles, a new therapeutic concept has been presented recently, which could be useful in patients encoding misfolded V_2 receptor mutants. Using the selective V_2 receptor antagonist SR 121463, a functional rescue of several different misfolded V_2 receptor mutants has been demonstrated. In line with this biochemical analysis, a clinical trial with patients suffering from congenital nephrogenic diabetes insipidus demonstrated that the V_1 receptor antagonist SR49059 reduced urinary output by 50% when compared to untreated controls.

It is assumed that the pharmacological agents support proper receptor folding, thus allowing the exit from the ER. Therefore, drugs with an ability to promote receptor folding are also termed *pharmacological chaperones* or *pharmacochaperones*. Whether these pharmacochaperones have the potential to be used broadly in nephrogenic diabetes insipidus remains to be seen. Another potential option for treatment, applicable to all patients with X-linked nephrogenic diabetes insipidus, is the stimulation of the cAMP/PKA-signaling cascade downstream of the V_2 receptor. PDEs, which degrade intracellular cAMP, represent one possible drug target. However, earlier clinical trials with rolipram, a selective inhibitor of the type 4 PDE, did not result in the reduction of the urinary output. Finally, gene therapy might be considered as a further treatment option. However, from the current point of view, gene therapy, in general, lacks safety.

Keywords

Amoebozoa
Eukaryotes can be assigned to one of eight major groups: excavates, discicristates, heterokonts, alveolates, cercozoa, plants, amoebozoa, or opisthokonts. Amoebozoa comprise lobose amoebas, dictyostelid slime molds, plasmodial slime molds, protostelid slime molds, and pelobionts.

Chemotaxis
Oriented movement toward a source of chemoattractant.

Development
Sequential changes in the gene expression program leading to cells with different properties.

Model Organism
Several organisms whose genomes are sequenced have been chosen by the National Institutes of Health (NIH) as model organisms for biomedical research to study the molecular mechanisms of cell motility, signal transduction, and cell-type differentiation and developmental processes.

Transformation
Introduction of foreign DNA into a cell in order to produce a protein or to interfere with gene expression.

Dictyostelium discoideum is a tractable system for the study of basic processes in cell and developmental biology. These processes include signal transduction, chemotaxis, motility, cytokinesis, phagocytosis, and aspects of development such as cell sorting, pattern formation, and cell-type differentiation. *Dictyostelium* has unique advantages for studying fundamental biological questions, since it is particularly amenable to both genetic and biochemical analyses. *Dictyostelium* has been chosen, along with several other organisms with known genomes, as a model system to analyze the functions of the identified genes. Biological questions in *Dictyostelium* have mainly

addressed the function of individual gene products, but more systematic approaches have now been launched on the basis of the knowledge derived from genome-, proteome-, and cDNA-projects. Recent studies on the genetics of *Dictyostelium* have opened new directions in biomedical research. This review summarizes the current knowledge on the *Dictyostelium* genome, updates the state of the *Dictyostelium* genome project, and concentrates on the molecular methods currently used to explore the functions of individual gene products.

1 *Dictyostelium* as a Model Organism

1.1 *Dictyostelium* – a Social Amoeba

The first reported species of the so-called cellular slime molds, *Dictyostelium mucorides*, was described by the mycologist Oskar Brefeld in 1869. Kenneth Raper subsequently introduced *D. discoideum* into the laboratory in 1935, and it has since become the most intensively studied species of the social amoebae. Other species of slime molds, such as *Polysphondylium pallidum*, have been poorly characterized. Cellular slime molds live as unicellular amoebae in decaying leaves of cool forest soil, where they feed on bacteria and other microorganisms by phagocytosis (Fig. 1a, b and Fig. 2d). *Dictyostelium discoideum* has been isolated in North America (Virginia, North Carolina, Massachusetts), in Europe, and in Japan.

As long as food is provided, *Dictyostelium* cells divide by mitotic cleavages (Fig. 2b, c). Starvation initiates a developmental program, which is accompanied by dramatic changes in gene expression. Starving cells stream toward a common center by chemotaxis, responding to and emitting cAMP signals (Fig. 1c and 2e). When about 100 000 amoebae have aggregated, they organize into a slug-shaped entity that can migrate toward light and can sense heat gradients (Fig. 1d). The slug then ceases migration and lifts off the substratum in a process called *culmination*. During this process, the cells differentiate into spore and stalk cells and form a fruiting body of 1 to 2 mm in height (Fig. 1e). Under appropriate nutritive conditions, new amoebae hatch from the spores (Fig. 2a) and the life cycle is started again. Alternative possibilities of resisting unfavorable environmental conditions are either the production of microcysts, a process about which very little is known, or macrocyst formation. During the latter process, cells of two mating types fuse under defined conditions, which include low ionic strength and starvation, and eventually a giant cell is formed. All three developmental options – formation of fruiting bodies, microcysts, and macrocysts involve the synthesis of cellulose walls that protect the cells against their environment.

The aspects of *Dictyostelium* development make it particularly amenable for research purposes. The developmental pathway is easily induced and reasonably fast, as it is completed within 24 h. Spores provide a convenient stage for long-term storage of cells, but the developmental cycle is not obligatory, since vegetative

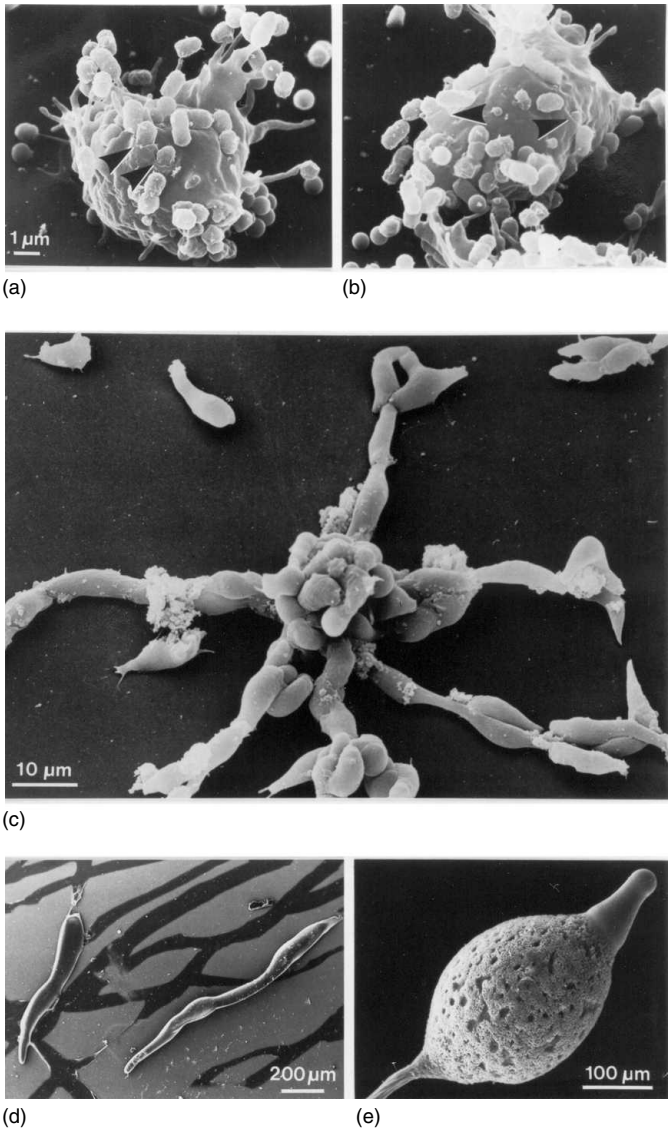

Fig. 1 Scanning electron micrographs illustrating different stages of the *Dictyostelium* life cycle: (a) and (b) amoebae feeding on bacteria by phagocytosis; (c) aggregating cells; (d) slugs moving on a solid substratum; (e) spore head of an almost completely differentiated fruiting body (Figure courtesy: M. Claviez).

cells can be frozen and maintained indefinitely in the laboratory. One of the great advantages of *Dictyostelium* is that it can be grown in the laboratory, not only on bacterial lawns but also on defined or semidefined liquid media, which enables mass production of genetically identical cells.

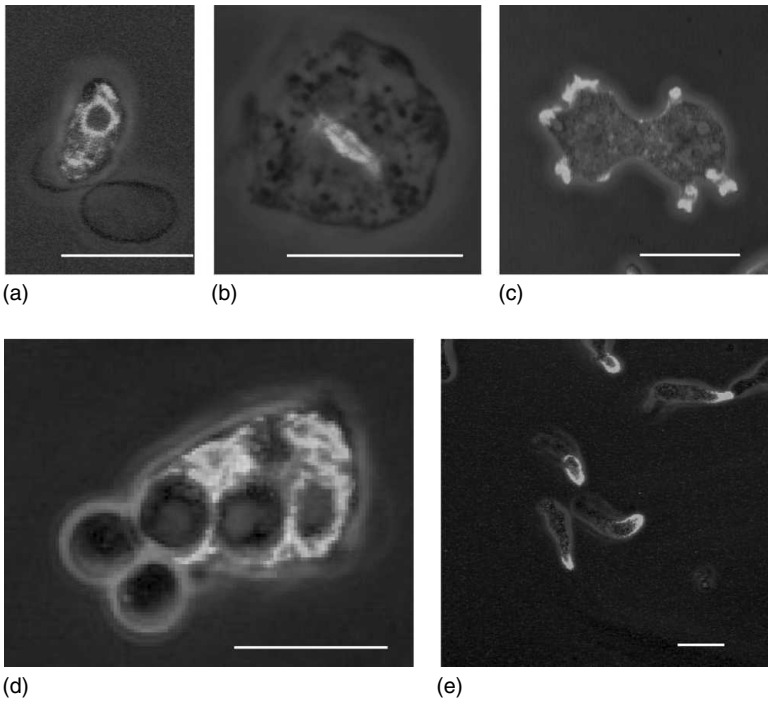

Fig. 2 Confocal micrographs of *Dictyostelium* cells illustrating (a) spore germination; (b) mitosis; (c) cytokinesis; (d) phagocytosis; (e) chemotaxis. GFP-tagged proteins were expressed in *Dictyostelium* to localize them within the cells during specific processes. (a) Calnexin-GFP was used as a specific marker for the endoplasmic reticulum (ER) and was imaged during germination of spores. The lower spore did not express the fusion protein. (b) Metaphase stage of mitosis; chromosomes were visualized by GFP-histone (green) and the spindle apparatus by antibodies directed against α-tubulin (red). (c) GFP-coronin, an actin-binding protein in the cell cortex, localizes to the distal cell poles during cytokinesis. (d) A *Dictyostelium* cell during the uptake of bacteria; GFP-calreticulin, a lumenal protein within the ER, was expressed to study the involvement of the ER in phagocytic cup formation. (e) *Dictyostelium* cells expressing a GFP-tagged kinase (DPAKa), which localizes to the rear end of the cells. Cells were moving in a gradient of cAMP toward the upper left corner. With the exception of (b) all images were taken using live cells. Bars, 10 µm (see color plate p. xxxiv).

1.2 Phylogeny of *Dictyostelium*

It is important to note that *Dictyostelium* amoebae can be considered as a prototype of a eukaryotic – a not yet specialized cell. Although historically called a *slime mold, Dictyostelium* bears little in common with other microorganisms like yeast or filamentous fungi, which have lost some or many proteins and pathways that are present in higher eukaryotes and also in *Dictyostelium*.

The phylogenetic position of *Dictyostelium* was, until recently, regarded as quite controversial. According to phylogenetic analyses based on combined protein data sets, *Dictyostelium* species are

now classified as Amoebozoa, positioned within the tree of life next to the Opisthokonts (Animalia and Fungi) and more distant from plants that diverged earlier. Accordingly, *Dictyostelium* genes show higher similarities to those of vertebrates than to those of plants or fungi.

1.3 Current Focus of *Dictyostelium* Research

The brief summary of the *Dictyostelium* life cycle already points to some main topics of research with this organism:

- chemotaxis
- signal transduction
- cytoskeletal research
- mitosis and cytokinesis
- phagocytosis
- mechanism of uptake of pathogenic bacteria like *Legionella*
- cell adhesion
- development, for example, cell differentiation and proportioning
- natural chimerism for investigation of issues relating to coexistence and conflict between cells
- homologs of human disease genes
- pharmacological studies

As a result of the continued work in these areas, *Dictyostelium* has been chosen by the National Institutes of Health (NIH, Bethesda) as a model organism for the study of the molecular mechanisms of signal transduction, cell motility, developmental processes and cell differentiation (http://www.nih.gov/science/models/).

DictyBase (http://www.dictybase.org/) is a web server that provides a comprehensive online resource for information on *Dictyostelium* research and is recommended for those who would like to get the most recent information on *Dictyostelium*. The web pages contain, for instance, genomics information, video images as well as protocols and methods. Furthermore, it provides a link to the most complete *Dictyostelium*-specific literature database available and a link to the currently built-up *Dictyostelium* stock center, which stores and distributes *Dictyostelium* strains and mutants as well as plasmids.

2 The *Dictyostelium discoideum* Genome

2.1 General Organization

The *Dictyostelium* genome is about 34 Mb in size and contains 6 chromosomes ranging from 4 to 7 Mb. Extrachromosomal elements comprise the mitochondrial DNA and the ribosomal DNA (rDNA) palindrome, which has been mistaken sometimes as a seventh chromosome. The chromosomes are believed to be acrocentric, with the centromere embedded in a cluster of long terminal repeat (LTR) retrotransposons (DIRS-1) composed of more than 40 elements.

The base composition of *Dictyostelium* is extremely biased toward a high adenine/thymine (A + T) content. On an average, the A + T content is 78%; in intergenic regions it may be as high as 98%. In coding regions, A and T residues are highly preferred in the third, or wobble position of the triplet. Coding sequences rather frequently contain repeats of the triplet AAC that encode depending on the reading frame polyasparagine, polyglutamine or polythreonine stretches. It is unclear if there is any functional role of these stretches in the respective proteins.

Dictyostelium genes are often simple in structure. Introns are infrequent and

their average length is about 130 bases, with larger introns of 1000 to 2000 bases occurring very rarely. Exon/intron junctions have the consensus splice sites AG/**GT**AAGT and AT**AG**/, with the bases printed in bold being absolutely conserved. The 3′ untranslated regions are on average not longer than approximately 150 bases. They contain a signal for 3′ processing and polyadenylation that corresponds to the mammalian AATAAA in most cases. Promoters are 1 to 2 kb in length.

The gene density with about 1 gene per 2.6 kb is quite high and similar to that of *Schizosaccharomyces pombe* (1 gene per 2.5 kb). For comparison, *Saccharomyces cerevisiae* has a gene density of 1 gene per 2.0 kb, whereas for human genes, the density is much lower and varies substantially across the genome between 6 and 23 per Mb.

Throughout most of its life cycle, *Dictyostelium* is a haploid organism, and therefore mutants can be easily generated (see Sect. 3). Nonetheless, one should keep in mind that a *Dictyostelium* cell is normally in the G2 phase of the cell cycle in which two sister chromatids already exist. Since the S-phase follows rather rapidly after mitosis, the G1 phase is extremely short.

2.2 The Mitochondrial Genome

Mitochondria of *Dictyostelium* carry a circular DNA molecule (mtDNA). The mtDNA contig is 55 564 bp in length and has been assembled from sequences contaminating the random shotgun reads of genomic DNA (http://dictygenome.bcm.tmc.edu) and by a primer walking strategy. It is significantly larger than mammalian mitochondrial genomes and hence more typical for protists (http://www.ncbi.nlm.nih.gov/genomes/static/euk_o.html). The A + T content of mtDNA, at 73%, is slightly lower than the one of genomic DNA. During vegetative growth, mitochondrial DNA can comprise up to 40% of the total cellular DNA.

The mitochondrial genome is transcribed into eight major, polycistronic RNA precursors encoding polypeptides, ribosomal RNAs (rRNAs), and interspersed transfer RNAs (tRNAs), which are processed into mono-, di-, or tri-cistronic RNAs. The maturation of polycistronic transcripts involves cleavage, using tRNAs as excision signals. The processing mechanisms are therefore similar to those reported for mammalian and fungal mitochondria and only rarely observed in higher plants. The complete sequence of the mtDNA revealed genes encoding 2 rRNAs, 18 tRNAs, 10 subunits of the NADPH dehydrogenase complex, apocytochrome b, 3 subunits of the cytochrome oxidase (COX), 4 subunits of the ATP synthase complex, 15 ribosomal proteins, and 5 other ORFs. In addition, a mitochondrial small (ms) RNA was identified in *Dictyostelium*. The msRNA is 129 nucleotides in length and is encoded by a mitochondrial gene. Although the predicted structure resembles that of 5S rRNA, the sequence shows only little homology with the mitochondrial 5S rRNA and the RNA is apparently not associated with ribosomes.

Sequence, gene content, and genome organization of the mitochondrial DNA of *Dictyostelium* displays similarities with the mitochondrial DNA of *Acanthamoeba castellanii*, based on sequence composition, gene content, and organization. In terms of phylogeny, it is important to note that in both organisms, the genes encoding COX1/2 are fused and the gene order within the ribosomal protein cluster is similar.

2.3 The Extrachromosomal rDNA Palindrome

In *Dictyostelium*, the genes that encode the RNA components of the ribosomes and the rRNAs are encoded by highly amplified multicopy families of identical genes that are carried on extrachromosomal palindromic elements that comprise up to 20% of the nuclear DNA. The sequence of the entire 88-kb rDNA element, which is present in about 100 copies per haploid genome, was determined recently. A chromosomal copy of the rDNA on chromosome 4 could provide the master copy for the stable transmission of the extrachromosomal elements. In nuclei of nocodazole-treated *Dictyostelium* cells that were arrested in mitosis, the extrachromosomal elements were found to form compact clusters. These clusters could ensure the efficient segregation of the rRNA to daughter cells during mitosis. They resembled true chromosomes in size and may thus explain previous cytological observations of a seventh chromosome in *Dictyostelium*.

2.4 Complex Repetitive Elements

Repetitive sequence elements are found in most genomes. They can be simple or complex, and if they are mobile, they are called *transposable elements*. Transposable elements carry direct or inverted repeat sequences at their ends and replicate within the genome. Transposable elements have no obvious function for the host cells, but probably contribute to genomic variability due to their transposition frequency within the genome.

The *Dictyostelium* genome hosts a series of complex repetitive elements that can be grouped into several classes. Together, these elements account for approximately 10% of the whole genome. Most complex repeats in *Dictyostelium* fit into commonly known classes of transposable elements. Some of them have been renamed recently and a summary on complex repeats in *Dictyostelium* has been published recently. The repeats are grouped into LTR retrotransposons, non-LTR retrotransposons, and DNA transposons.

LTR retrotransposons comprise DIRS-1 and *gypsy* class elements. DIRS-1 (also named Tdd1), had already been detected in the early days of exploration of the *Dictyostelium* genome. DIRS-1 is the most frequently found retrotransposon and makes up more than 3% of the genome. It encodes a retrovirus-like reverse transcriptase, and is flanked by inverted repeats. DIRS repeats are clustered in the vicinity of centromeres. DGLT-A and skipper are *gypsy* class transposable elements carrying direct repeats at their ends.

Non-LTR transposons are classified into TRE3 and TRE5 elements, so named as they insert in a position- and orientation-specific manner into the genome and integrate preferentially about 50 bp upstream (TRE5) or about 100 bp downstream (TRE3) of tRNA genes. On chromosome 2, for instance, TREs have spread and are found adjacent to about 75% of the tRNA loci present. TRE5 can be also used for gene-targeted retrotransposition.

DNA transposons are elements that are excised and inserted into new genomic locations without amplification. This new class of elements, including Tdd-4, Tdd-5, and DDT transposons, has only recently been identified in *Dictyostelium*. Thug elements have no coding capacity and carry terminal inverted repeats.

2.5 Nuclear Plasmids

Endogenous plasmids have been isolated from many wild-type strains of *D. discoideum*, for instance, NC4 or Ohio, or from related *Dictyostelium* species like *D. purpureum*. These plasmids range in size from about 1.3 to 30 kb and have copy numbers of 50 to 300 molecules per cell. The *Dictyostelium* plasmids are located within the nucleus and have a nucleosome structure that is typical for histone-associated DNA. The number of copies of each plasmid is dependent upon the individual plasmid, and remains stable over time. This copy number is independent of the genetic background of the strain and is constant relative to the degree of ploidy. Unlike the 2 μm circle of *Saccharomyces*, the different strains of *Dictyostelium* harbor different, nonhomologous plasmids.

In *D. discoideum*, two major plasmid families are distinguished – Ddp1 and Ddp2, and newly found plasmids can be grouped into either class. Previous studies have shown that Ddp1 carries an origin of replication within a 543-bp region, and its plasmid-encoded gene products are essential for long-term maintenance of the plasmid but not for replication. Ddp2 carries two elements that are essential for its extrachromosomal replication. It encodes the so-called Rep protein, a transactivator that interacts with a cis-acting DNA sequence, which is located in a 592-bp region of an inverted repeat. This element ensures extrachromosomal replication when the transacting factor is expressed. Studies showed that the Rep protein is not essential for autonomous replication, but it is likely to be involved in transcriptional regulation, control of DNA replication, and amplification of plasmids at low copy number.

2.6 Small Noncoding RNAs

Recently, several small noncoding RNAs (ncRNAs) were identified in *Dictyostelium* by utilizing an unbiased shotgun approach in combination with bioinformatics. Small RNAs of about 50 to 500 nucleotides length were isolated, followed by construction of cDNA libraries representing full-length small RNAs. Different classes of RNAs were identified, for example, putative small nucleolar RNAs (snoRNAs), small nuclear RNAs (snRNA), and a signal recognition particle RNA (SRP-RNA). In addition, an abundant novel class of RNAs (~50 to 65 nucleotides) was identified, which had previously not been identified in any other organism. These RNAs have conserved 5′ and 3′ ends that are complementary to each other and are predicted to base-pair and to form a stem-structure. Such structures are common motifs within different classes of functional ncRNAs, suggesting a biological role for these novel RNAs. Interestingly, these RNAs seem to be downregulated during development, suggesting a biological role for these novel RNAs.

2.7 Sequencing Projects

2.7.1 The *Dictyostelium* Genome Project

The sequencing and analysis of the genome of *Dictyostelium* (strain AX4) is an international collaboration between research groups in Germany, the United Kingdom, and the United States of America (see Table 1) (see also http://www.dictybase.org/). The project was started in 1998, and currently all

Tab. 1 Dictyostelium chromosomes and status of the genome project.

Chromosome	*Size [Mb]*	*Number of genes*	*Status*	*Contributing groups*
1	5.5	1784	Finished	1, 2
2	6.9	2799	Published	1, 2
3	5.3	2000	Shotgun complete/finishing	1, 2, 3
4	6.2	2300	Shotgun complete/finishing	3, 4
5	5.3	2000	Shotgun complete/finishing	3, 4, 5, 6
6	4.1	1500	Finishing	1–7

Notes: Sizes of the chromosomes are based on YAC mapping. The number of protein-coding genes per individual chromosome was either predicted from the completed sequence (chromosomes 1 and 2), or estimated on the basis of chromosomal sizes and gene density determined for chromosomes 1 and 2. Groups contributing to the *Dictyostelium* sequence consortium: (1) University of Cologne, Cologne, Germany (http://www.uni-koeln.de/dictyostelium/); (2) Genome Sequencing Center, Jena, Germany (http://genome.imb-jena.de/dictyostelium/); (3) Baylor College of Medicine, Houston, United States of America (http://dictygenome.bcm.tmc.edu/); (4) Sanger Institute, Hinxton, United Kingdom (http://www.sanger.ac.uk/Projects/D_discoideum/); (5) University of Dundee, Dundee, United Kingdom; (6) Medical Research Council, Cambridge, United Kingdom (http://www.mrc-lmb.cam.ac.uk:80/happy-homepage.html); (7) Pasteur Institute, Paris, France.

contributing groups have now pooled their data sets for a whole genome assembly, suggesting that the complete genome will be available in 2004. Goals of the genome project are to establish a comprehensive gene catalog and to provide functional analysis of these genes using, for instance, microarrays.

To sequence the *Dictyostelium* genome, a whole chromosome shotgun was employed following the separation of the chromosomes using pulse-field electrophoresis. DNA segments were subcloned either into yeast artificial chromosomes (YACs), or the DNA was sheared and cloned into pUC vectors. Shotgun sequences were assembled by a seed- and BLAST-based cyclic assembly strategy. To order the contigs along the chromosomes, HAPPY map, an *in vitro* PCR-based method that examines the cosegregation of sequence-tagged site markers in a panel of randomly broken genomic DNA, was employed. The program Phusion enabled computer-assisted readpair-based assembly. Previously mapped genes and a circular YAC library were also used to validate the assembly. The total coverage of the genome is now about 10-fold. The high A + T content, the presence of low-complexity intergenic regions, and the large number of complex repetitive elements complicated the sequencing and assembly of the *Dictyostelium* genome significantly.

Gene prediction and annotation of chromosomes 1 and 2 was initially performed using GlimmerM, a partially trained program, and continued with GeneID, trained with 160 previously known *Dictyostelium* genes. The latter version was fine-tuned for *Dictyostelium* genes taking into account features common to promoters, splice signals, and polyA signals. Gene ontology system (http://www.geneontology.org/) was used for a computer-assisted classification of genes homologous to genes of other organisms. About 70% of the genes match

known sequences and can be grouped into categories describing cellular processes and/or molecular functions.

For the *Dictyostelium* genome, a total number of about 12 000 genes is expected (see Table 1). This is approximately twice as much as in yeast, and close to the number of genes in *Drosophila* (13 600). The estimated gene number in *Dictyostelium* also provides a good estimate for the number of encoded proteins (the proteome), as only a few genes are known that use differential promoters, alternative splicing, or regulated 3′ processing to make alternative gene products.

An overview on the *Dictyostelium* chromosomes and the status of the genome project is given in Table 1. Chromosome 1 is 5.5 Mb in size encompassing 1784 protein-coding genes. Its sequence analysis is completed. Chromosome 2 is the largest of the *Dictyostelium* chromosomes comprising 6.9 Mb and representing about 20% of the genome. It was the first *Dictyostelium* chromosome for which the complete sequence was reported. Analysis revealed that it codes for 2799 predicted protein-coding genes and 73 transfer RNA genes. For chromosome 3, shotgun sequencing is finished and the assembly has started. Chromosomes 4 and 5 comigrate in the pulse-field electrophoresis and were therefore processed together. Chromosome 6 is the smallest one with 4.1 Mb and approximately 1500 genes are expected. In an analysis of the structural features of this chromosome, DIRS repeat clusters of about 50 to 180 kb were detected at each chromosome's end, supporting the assumption that *Dictyostelium* chromosomes are telocentric.

2.7.2 The *Dictyostelium* cDNA Project

Several Japanese universities are involved in a collaborative project to identify and analyze expressed genes in *Dictyostelium* (http://www.csm.biol.tsukuba.ac.jp/cDNAproject.html). The goal of the project is to identify and characterize genes of *Dictyostelium* in distinct stages of growth and development to provide essential information regarding the structure, function, timing, and composition of expressed genes.

Initially, the project started with EST (expressed sequence tag) libraries constructed from size-fractionated growth- and slug-stage specific cDNAs. Sequences were analyzed by BLAST and PHRAP programs to obtain a set of nonredundant ESTs. The EST libraries were of great value for discovering genes and for analyzing their expression profile. To complement the gene identification by large-scale EST analysis, full-length cDNA libraries were constructed by an oligo-capping method starting with RNA from vegetative, aggregation, migration, and culmination stages. About 90% of the cDNA clones obtained in each set were full length. The sequences of more than 70 000 cDNA clones were obtained and analyzed. From the data sets, 8361 nonredundant sequences and 6718 assigned genes were determined (contig version 5.0). Partial cDNA clones from vegetative (VS-clones), developmental (SL- and SS-clones), and sexual (FC-, FCL-, and FC-IC-clones) stages as well as full-length clones are available and can be requested for conducting further work.

Furthermore, the cDNA project is directly linked to ATLAS, a spatial expression database containing results from *in situ* hybridization studies. Clones of the cDNA project have been used in microarray analyses in order to characterize both developmentally regulated and cell-type specific genes. In addition, whole-mount *in situ* hybridization was employed to study changes in the expression pattern of prestalk cells

based on the abundance of established cell-type specific genes from microarray results.

2.8 Transcriptome and Proteome Approaches in *Dictyostelium*

The developmental cell cycle of *Dictyostelium* is accompanied by a series of coordinated morphological and physiological changes. There is a general interest as to whether these transitions can be correlated with changes in gene expression and also protein levels. One way to examine if coregulated genes share functional characteristics, or if the expression pattern reflects the cell's physiology, is to apply transcriptional profiling using microarrays.

This approach was recently applied to *Dictyostelium*, using a collection of 7385 cDNA clones that represent about two-thirds of the expressed protein encoding genes. This analysis revealed that major developmental events coincide with prominent transcriptional changes. A significant change in the expression of more than 25% (2000 to 3000) of the genes takes place during the aggregation stage. This compares with changes in the preaggregation period and the finger stage of morphogenesis in which only little changes were detected. The transcriptional profile itself seems to be robust, as it is independent of the previous nutritional state and the strain investigated. Microarrays have also been used successfully to identify new cell-type specific genes preferentially expressed either in prestalk or prespore cells that can serve as useful markers for the characterization of cell types, or to investigate gene regulation during early development.

Proteomics involves the systematic separation, identification, and characterization of proteins present in a cell, tissue, or other biological sample. The collection of proteins may be correlated with a certain physiological state or might be helpful to determine diseases at a molecular level. In studies of single-cell organisms like *Dictyostelium*, however, proteomic approaches can also be used to analyze the proteins associated with entire organelles like phagosomes, or prespore secretory vesicles to enhance the understanding of the endocytic pathway or the mechanism of regulated secretion. SWISS-2DPAGE (http://www.expasy.org/ch2d/publi/dicty.html) offers a published 2D-PAGE map of *Dictyostelium*.

3 Tools for Molecular Manipulation

As a model system, *Dictyostelium* is used to investigate the functions that underlie biological processes. In the past, this had been done by mutagenizing cells with radiation or chemicals like nitrosoguanidine, and selecting mutants of interest for further investigation. Some of these mutants were subjected to additional rounds of mutations to build up elaborate regulatory networks, but details of the molecules underlying these processes often remained unknown. Many research groups have tried to complement this type of mutant with expression libraries, but this approach has frequently failed, although there is one report on a recent success. At present, most molecular studies investigate the function of individual proteins, but more systematic approaches have been launched on the basis of knowledge derived from genome-, proteome- and cDNA-projects.

3.1
Transformation and Selection

The career of *Dictyostelium* as a molecular model system started almost 20 years ago, when Nellen and coworkers developed transformation vectors and devised a protocol for transformation and selection of axenic cells. In principle, this method is similar to a technique used for transformation of mammalian cells, in which cells adhering to a culture dish are overlaid with a calcium precipitate containing many copies of the transforming DNA. Cells are then osmotically stressed for a few minutes by the addition of glycerol, which results in the internalization of the DNA, and its integration into the nuclear genome. This method has been continuously improved and is still used in many labs around the world. Subsequently, two alternative methods have been established. Electroporation allows the introduction of single or a few vector copies into the cell. This technique is important if vectors containing libraries are to be transformed. More recently, a ''gene gun'' has been applied for transient transfection experiments. Here, metal particles are coated with DNA and ''shot'' into the cells. In principle, this method bears the potential to target the mitochondrial genome as well as the nuclear DNA.

Transformation efficiencies of these methods are, however, low, giving in the order of 10^{-5} cells that carry the desired foreign DNA per experiment. These rare transformants can be enriched by metabolic selection for mutants in the biosynthetic pathway of nucleotides. Alternatively, transformants are selected for resistance to antibiotics like hygromycin, bleomycin, geneticin (G418), and blasticidin, of which the last two are most commonly used. Different antibiotics require different amounts of enzyme for their inactivation. Therefore, the transforming DNA is found to be amplified to varying degrees in the resistant cells.

3.2
Transformation Vectors

We now need to consider the different characteristics of the vectors used for transformation. If the plasmid bears a replication origin specific for *Dictyostelium* and encodes accessory factors (see Sect. 2.5), it remains extrachromosomal and is propagated autonomously. The majority of circular plasmids, however, lack these features. Accordingly, they are integrated into the genome and segregate with the chromosomes. A detailed analysis by Barth et al. has revealed that when a circular plasmid enters the nucleus, it becomes replicated by a rolling circle mechanism and the multimeric product is integrated into a single site into the genome. If more than one plasmid enters a cell, which is a known and sometimes desired consequence of calcium precipitation, they may end up in different chromosomal locations. The final copy number obtained after amplification varies between 1 and 1000, but the selection regimes using different antibiotics result in the survival of low copy numbers ($\ll$10) for blasticidin and high copy numbers (50–200) for geneticin. Integration is also inevitable if linear DNA fragments are used for transformation instead of circular plasmids.

There are two applications for the molecular manipulation of cells: one is to obtain cells with additional features (gain-of-function mutant). The other reason is to construct strains lacking a certain cellular property (loss-of-function mutant). There are many ways to achieve these goals,

and most of them require plasmids that allow a certain degree of control over the expression levels in time and space. Some plasmids use naturally regulated promoters from the *discoidin* I *gamma* or *actin* 6 genes, which are much more active in axenically growing cells than in cells feeding on bacteria, but a promoter active in bacterially growing cells is also available. Promoters that provide easier control over their expression level are, for example, repressible by the natural chemoattractant folate or inducible by the bacterial antibiotic tetracycline. For mRNA expression, specifically in the aggregation stage of the *Dictyostelium* life cycle, a vector is available that uses the promoter of the cell adhesion protein contact sites A. This promoter can be superinduced by extracellular pulses of the chemoattractant cAMP. In later phases of development, cell-type specific promoters can be used like those expressed in prespore cells and different types of prestalk cells. However, for many applications, a nearly constitutive promoter like the one from the *actin* 15 gene may suffice.

3.3 Pathways of Molecular Manipulation

The possibilities of genetic manipulation that have been exploited in *Dictyostelium* cells to date are summarized in Fig. 3.

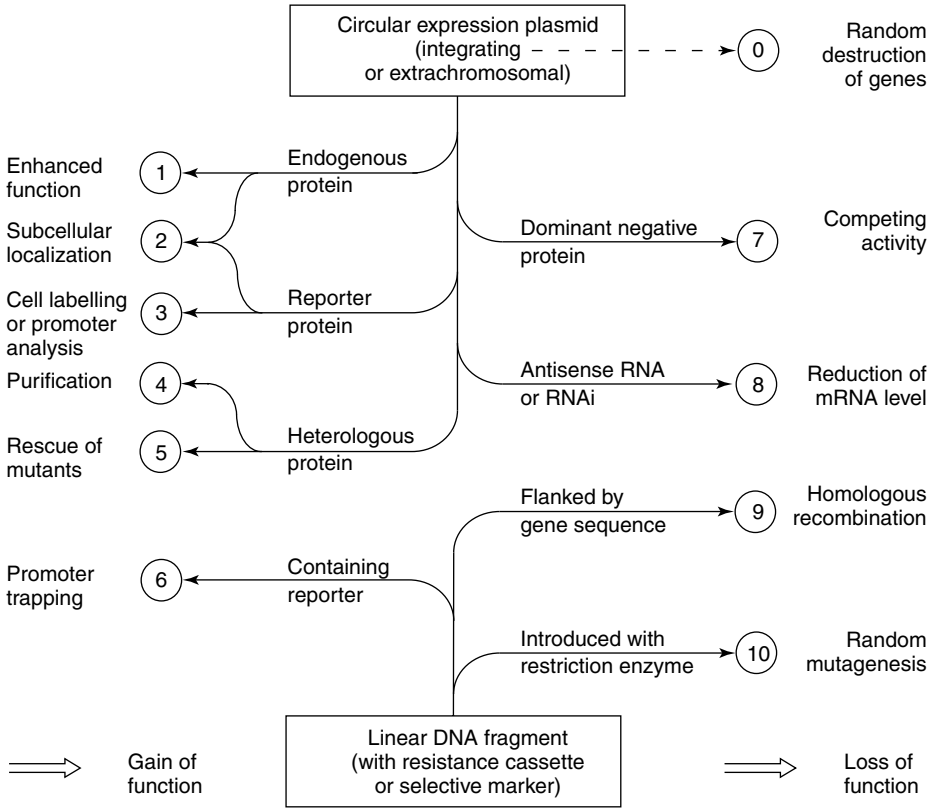

Fig. 3 Pathways of molecular manipulation. See text for detailed description.

Below, we discuss the individual options step-by-step, using applications illustrated with one or a few citations rather than providing a complete listing of the available literature.

3.3.1 Gain-of-Function Approaches

The aim of transforming *Dictyostelium* cells with expression vectors is to express either homologous native or mutated genes, often containing an introduced marker protein. *Dictyostelium* can also be used to express genes derived solely from heterologous organisms. Because many transformation vectors integrate randomly into the genome and may accidentally destroy genes (Fig. 3, path 0), it is advisable to analyze a number of clones obtained from independent transformations for the absence of growth defects and developmental abnormalities.

Overexpression of endogenous proteins In many cases, endogenous proteins were overexpressed just to increase the efficiency of their purification. Looking at the phenotypes of overexpressing cells, one is also tempted to interpret observations as possible clues for protein function (Fig. 3, path 1). This may indeed be feasible in an ideal situation in which the phenotype of overexpressing cells is the reverse of cells lacking the protein. Unfortunately, this correlation only holds true if the effect that is studied is directly caused by the protein under investigation. In contrast, there are also reports revealing that overexpression of a protein and its loss produce similar phenotypes. Results of this sort suggest that for many biological processes there is an ideal concentration of the components involved and tipping the balance to either side perturbs the molecular pathway.

Expression of reporter proteins Many different reporter proteins have been expressed in *Dictyostelium* (Fig. 3, path 3). These experiments served to provide quantitative measures for promoter activity and were used to dissect functional promoter elements. Here, the firefly luciferase, bacterial beta-galactosidase, and chloramphenicol acetyltransferase were most frequently used for quantification. On the other hand, reporter proteins were used to label entire cells for studies on their behavior in the multicellular stage of development. Beta-galactosidase was the protein of choice for a long time, because it can be easily detected and its lifetime can be manipulated. More recently, the green fluorescent protein (GFP) and its variants, which can be visualized without fixing and staining cells, have taken over, thus allowing the fates of living cells to be tracked. The GFP reporter protein has proven to be especially useful for producing chimeras with endogenous proteins to study their subcellular localization (Fig. 2 and Fig. 3, path 2). Using this approach, virtually all known compartments and organelles have been tagged to allow their fluorescence-mediated detection in living cells.

Expression of (other) heterologous proteins The relative ease of expressing genes from other organisms conferring resistance to antibiotics or acting as reporters has stimulated interest to use *Dictyostelium* cells as a eukaryotic expression system (Fig. 3, path 4). It was found, however, that it was necessary to change the first few codons of heterologous genes into *Dictyostelium* codon usage, especially if G or C residues are frequent in the wobble position. Then, antigens from parasites or viruses, or proteins of medical importance can be successfully expressed. The

Dictyostelium system may also become important to express functional membrane proteins and glycoproteins. The requirements for glycosylation have been recently established and various glycosylation mutants are available. Most recently, one important prerequisite for large-scale production has been achieved when Flaschel and coworkers succeeded in growing cells in a conventional bioreactor to high densities in an improved medium. In addition to these more technological aspects, expression of heterologous genes has been used to rescue *Dictyostelium* cytoskeletal mutants with proteins from other organisms like plants or animals (Fig. 3, path 5).

3.3.2 Loss-of-Function Mutations

In order to study the role of a protein *in vivo*, it is often illuminating to investigate cells that lack its function. This goal can be achieved using one of three targeted approaches.

Dominant negative effects In rare cases, there is detailed information available on the protein's crystal structure, or previous work in other organisms has identified functionally important amino acids. Then one can reconstruct single point mutations creating dominant negative mutants (Fig. 3, path 7), which are generally used for the functional analysis of small GTPases involved in regulating the cytoskeleton, vesicle trafficking steps, or other events in signal transduction. Similarly, one can guess whether a domain of the protein like the myosin tail will interfere with the endogenous protein forming inactive complexes or a myosin power-relay mutant will block the actin target by high-affinity interaction.

Antisense RNA and RNA interference The expression of antisense RNA has been used to interfere with gene expression posttranscriptionally, thus creating a type of gene knockout strain. In this method, a fragment of the gene of interest is inserted in opposite orientation behind a promoter of an expression plasmid so that it is transcribed into the noncoding strand. It was assumed that this RNA forms a base-paired hybrid molecule that becomes degraded within the cell, since neither endogenous mRNA nor antisense RNA could be detected in successful gene ablation attempts (Fig. 3, path 8). More recently, the novel approach of RNA interference (RNAi) was established for *Dictyostelium* (Fig. 3, path 8). Here, a self-complementary, hairpin-structured RNA molecule is transcribed, which acts both as a signal and cofactor in the pathway of enzyme-mediated destruction of the corresponding endogenous mRNA. Antisense RNA and RNAi techniques have two major advantages. First, they are suitable for the elimination of all of the mRNAs and protein products of a gene family, and secondly they provide the chance to isolate hypomorphous mutants in essential genes, which express just the minimum amount of the gene product required for cell survival.

Gene disruption by homologous recombination Undisputedly, the most precise tool to study a protein's function *in vivo* is the production of a null mutant. This has become feasible when De Lozanne and Spudich attempted to overexpress a truncated myosin molecule and the resulting phenotype indicated a total loss of function. Closer analysis of the mutant revealed that the vector had integrated by homologous recombination and disrupted the myosin gene. Since then, many genes have

been ablated using resistance cassettes or metabolically selectable markers that replace an essential part of the gene (Fig. 3, path 9). Technically, the assembly of gene replacement constructs has become easier by two novel techniques. The first one is based on a PCR approach that works without conventional cloning steps such as ligation and transformation into *Escherichia coli* hosts. The second method for constructing replacement fragments uses the reaction of Tn5 *in vitro* transposition into a genomic fragment carried in a plasmid, allowing the subsequent isolation of disruption vectors after transformation of *E. coli*.

Because gene replacement requires two independent crossover events within the two flanking homologous sequences, it is a relatively inefficient event. To enhance the success rate, a linear DNA fragment rather than a circular plasmid is used. To prevent a possible circularization *in vivo*, the ends of the transforming DNA can be modified by dephosphorylation or the addition of dideoxynucleotides. In addition, a negative selection regime can be used to reduce random insertion: a gene encoding a tRNA molecule suppressing the most frequent stop codon in *Dictyostelium* (UAA) is appended outside the homologous regions of the gene. After transformation and integration, only those cells that have lost this lethal factor by a crossover event will survive.

Gene replacement strategies do not inevitably lead to all-or-none results. A couple of approaches allow for the construction of conditional mutants or cells producing residual protein activity, which is especially useful for the investigation of essential gene products. Parts of the *NSF* gene, which plays a role in the essential process of membrane fusion, have been randomly mutated, and the endogenous copy of the gene has been replaced with this library to select a temperature-sensitive mutation. Using an even more ambitious approach, the chromosomal copy of the DNA-binding factor CMBF has been exchanged with a mutated version containing an in-frame UAG stop codon within the coding region. This UAG codon is rarely used by native *Dictyostelium* genes, therefore, the cells apparently tolerate the expression of a cognate suppressor tRNA; but because suppression is inefficient, the cells contained strongly reduced amounts of CMBF, so that its function could be finally investigated.

3.3.3 Random Mutagenesis

Because random approaches produce large numbers of mutants, it is especially important to develop efficient selection or screening regimes. The easiest way is, of course, to select for mutants that survive a drug treatment or are able to develop in the presence of a drug. Elegant strategies have been used to enrich mutants impaired in phagocytosis or cell adhesion. If changes in the expression of a single gene are the output of a mutagenesis experiment, colony blot techniques can be used to detect the expression of a protein by antibodies or by hybridization to endogenous mRNA. If none of these approaches can be used, mere visual inspection of clones growing on bacterial lawns may identify mutants that are defective in the completion of development.

Promoter traps While the molecular approaches discussed so far all rely on some knowledge of the gene product to be manipulated, there are some methods that are suited to target even unknown genes in a genome-wide manner. One of these methods is the random knockin strategy of a promoterless reporter gene to identify stage-specific and developmentally

regulated transcription units by virtue of the gain in reporter activity (Fig. 3, path 6). Of course, by applying the appropriate selection regimes, this method can also be used for the isolation of loss-of-function mutations.

Restriction enzyme-mediated integration For functional analysis of a biological process, it is essential to saturate the genome with mutations in addition to tagging genes for subsequent identification. In this respect, the method of restriction enzyme-mediated integration (REMI) has proven to be especially useful. For REMI, a linearized vector is transformed into the cells, together with a restriction enzyme producing compatible ends. The enzyme cleaves chromosomal DNA at random positions and the linearized vector integrates into the restriction site during the repair process. This method was initially applied to isolate developmental mutants. Subsequently, the protocol was optimized through integration of vectors bearing the blasticidin resistance cassette into the more frequent DpnII sites of the *Dictyostelium* genome. To recover the mutated gene, a preparation of genomic DNA is digested with a restriction enzyme that cuts outside the vector and is then ligated and transformed into *E. coli* cells. Thus, sequences flanking the insertion site are recovered and the resulting plasmid can be immediately used to reconstruct the mutation in a wild-type background to confirm the original phenotype.

Shotgun antisense A conceptually related approach to producing random mutations is the transformation of cells with an expression library of *Dictyostelium* cDNAs inserted in reverse orientation with respect to the promoter, so that antisense RNA molecules are produced (see also Fig. 3, path 8). The antisense strategy is associated with a couple of problems, because it favors the isolation of genes that are overrepresented in the antisense library. However, this shotgun approach has been used to successfully identify genes involved in the completion of the developmental cycle of *Dictyostelium*.

3.4 Complex Mutants

Basically, the strategies discussed above lead to cells with a single genetic alteration. When a mutant strain constructed by homologous recombination is complemented with a plasmid that restores expression of the missing protein, for example, from a different promoter, a second level of complexity is reached. However, to obtain such cells, two different selectable markers have already been employed. Therefore, the construction of even more complex mutants is a challenging task. In some cases, knowledge about the chromosomal organization of the genes in question may help. It was found that all four members of the GP138 gene family were arranged in tandem, so a total tetra knockout could be created in one go. In most cases, however, the genes to be analyzed are spread throughout the genome. If they turn out to reside on different chromosomes, one can use parasexual genetics to produce crosses between mutants as used previously for the combination of chemically induced mutations. More recently Insall and King have devised protocols for producing diploids in axenic cultures and subsequent haploidization. They showed for the first time the successful combination of two gene disruption mutants obtained by molecular methods.

In order to construct multiple knockouts using the same resistance mechanism for each single step, the cre/lox system is currently exploited in a couple of laboratories. In this approach, the resistance cassette is directly flanked by two bacteriophage-derived *loxP* sequences that are recognized by the cre recombinase. After successful gene disruption, the resistance cassette can be excised by the cre enzyme to provide a strain that is again sensitive toward the selective antibiotic, which can be used in another round of targeted homologous recombination. Finally, one should not forget that when the goal is not disrupting multiple genes but rather expressing two different proteins within a single cell, cotransformation may be the method of choice. In this approach, two different plasmids, which can even bear the same selectable marker, are transformed simultaneously. Irrespective of whether the precipitation and osmotic shock method or electroporation is used, many cells will receive both plasmids that integrate independently into different chromosomal locations. They may accordingly be amplified to different degrees. In the end, one can choose among a number of clones and identify the ones that produce the desired expression levels of both proteins.

4 Outlook

For roughly a century, *Dictyostelium* has served as an excellent model system for biological research. During this time, the fundamental goals of research using this organism have changed. Initial studies in areas of developmental biology such as the determination of cell fate or the maintenance of body proportion has become more focused on the underlying topics such as cell adhesion processes and signal transduction. The last decade has seen the opening up of both the entire genome and the regulation of genes within the genome. Valuable information gained over this period is now being employed for functional studies of this simple eukaryote that is equally amenable to both genetic manipulation and biochemical analysis. It will contribute significantly to basic research in areas such as biomedicine. Results obtained with *Dictyostelium* will continue to influence the research in other fields and vice versa. This will ensure the continued use of *Dictyostelium* to solve the questions posed by modern biology.

Acknowledgments

We would like to thank Fredrik Söderbom (Swedish University of Agricultural Sciences, Uppsala, Sweden) for communicating results on small RNAs in *Dictyostelium*, Ludwig Eichinger (University of Cologne, Germany) for providing information on the genome project prior to publication, and Wolfgang Nellen (University of Kassel, Germany) for comments on the manuscript.

Keywords

Dimerization
Covalent bonding of adjacent purine or pyrimidine bases resulting from the resolution of the unstable electronic configuration created by absorption of a photon within the UVR range of light.

Endonuclease
An enzyme, often associated with the excision repair process that cleaves a phosphodiester bond to either the 3′ or 5′ side of a base or abasic site in DNA.

Nucleotide Excision Repair
Replacement of damaged DNA with nascent, corrected DNA involving recognition, unwinding, incision, excision, resynthesis, and ligation.

Photohydrate
A type of monobasic photoproduct to which a hydroxyl (–OH) group has been added to the 5 or 6 carbon of a pyrimidine base.

Photoenzymatic Repair (PER)
A light-dependent process involving the enzyme-catalyzed reversal of CPDs.

Photoproduct
A stable change in DNA structure involving a single base or adjacent bases resulting from the dissipation of absorbed UVR.

Reactive Oxygen Species (ROS)
Highly reactive, short-lived chemical species containing oxygen formed by the interaction of ionizing or nonionizing radiation with water.

Ultraviolet Radiation (UVR)
Wavelengths of the electromagnetic spectrum ranging from 190 nm to 400 nm; UVR is subdivided into vacuum UV (190–240 nm), UVC (240–290 nm), UVB (290–320 nm), and UVA (320–400 nm).

Xeroderma Pigmentosum
A rare autosomal recessive disease, displaying sun sensitivity resulting in progressive degenerative changes in sun-exposed portions of the skin and eyes, often leading to neoplasia.

It has been known for more than a hundred years that ultraviolet radiation (UVR) can have adverse effects on the growth and development of living organisms. Degradation of stratospheric ozone and the resultant increase in UVB radiation at the earth's surface has focused our attention on the public health and environmental effects of solar DNA damage. With the advent and advancement of molecular biology over the past three decades, our understanding of the biochemical foundation of the cytotoxic, mutagenic, and carcinogenic effects of UVR has greatly increased. Armed with an arsenal of powerful techniques, today's researchers are able to probe the intricate structure of UVR damage induction and repair in DNA. Indeed, recent advances in deciphering DNA repair in bacteria, yeast, and humans have greatly increased our understanding of the molecular mechanisms underlying this complex and essential process. In concert with public awareness and political action, the adverse effects of global stratospheric deozonation can be mitigated by the development and application of basic photobiological research.

1 Effects of UVR on Living Systems

UVR damage in cellular DNA can be resolved in several ways (Fig. 1), depending on the type of lesion produced, the genomic location of the damage, the type of cell affected, and the developmental state of the cell. It is plausible that some lesions are not perceived as different from normal DNA by the cell. However, it is more probable that, unless the damage is repaired, it will disrupt the normal operation of vital cellular processes such as DNA replication or transcription. In this event, cell proliferation will cease or, if the lesion is situated in a gene required for an essential metabolic function, the cell will die.

Some types of photodamage are more effective than others at blocking the progression of DNA or RNA polymerases. Types of DNA damage that facilitate lesion bypass by the replication machinery may allow misincorporation of an incorrect complementary base, thus producing a mutation. A mutation may have several outcomes. First, it may be benign, neither altering the genetic code nor affecting normal metabolism. Second, the mutation may create a truncated or partial RNA transcript and a dysfunctional protein. If the protein is essential, then the mutation is lethal. Finally, it may result in activation of an oncogene or inactivation of a tumor suppressor gene, resulting in the initiation of cell transformation and carcinogenesis.

Although a direct role of DNA damage in replication and transcription is well documented, other pathways in which DNA damage can affect cell rate and metabolism have been described and operate through various signal transduction pathways. For instance, DNA damage in the skin resulting from extended exposure to solar UVR is implicated in immunosuppression, erythema (sunburn), and photoaging. On a more global scale, increased DNA damage in the environment resulting from decreases in stratospheric ozone has been linked to reduced productivity in marine ecosystems, effects on food crops, and livestock and has been implicated in the global amphibian decline.

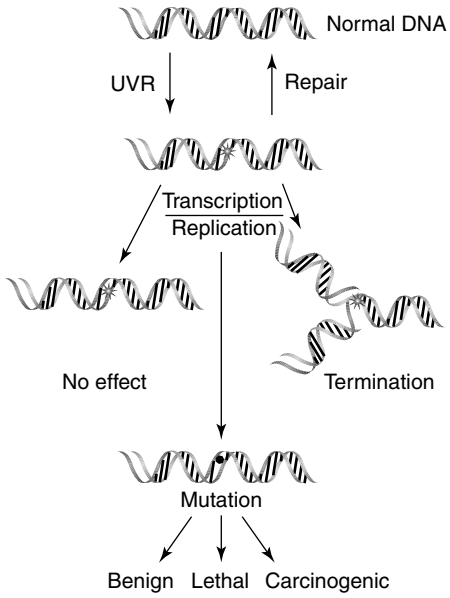

Fig. 1 Biological consequences of UVR. Molecular events that lead to cell killing, mutation induction, and carcinogenesis are shown.

2 The Electromagnetic Spectrum

The sun emits a broad array of energies at wavelengths ranging through 11 orders of magnitude from 1 nm to 100 m (Fig. 2). Much of this energy is biologically irrelevant; long wavelength, low energy emissions such as far infrared and microwaves are highly unlikely to impart sufficient energy to influence biochemical reactions. Likewise, visible and near infrared wavelengths, although very important for vision and photosynthesis, are not considered hazardous to living organisms. Finally, ionizing radiations such as high-energy particles, X-rays, and gamma rays are expended by atomic collisions in the upper atmosphere. Hence, UVR emerges as the most biologically relevant component of the solar spectrum with respect to DNA damage.

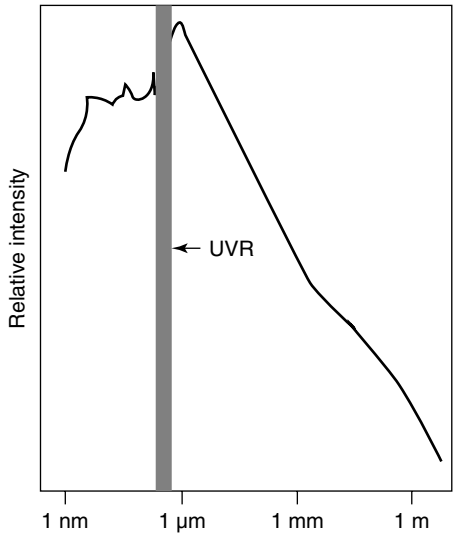

Fig. 2 The electromagnetic spectrum. Energy emitted by the sun is shown for wavelengths between 1 Å and 100 m. The ultraviolet spectrum (190–400 nm) is indicated by the shaded line.

The UV spectrum is divided into three regions: UVC (240–290 nm), UVB (290–320 nm), and UVA (320–400 nm). Because of their high energies and availability, germicidal (UVC) lamps have historically been used for photochemical and photobiological studies. However, since the earth's atmosphere absorbs UVR wavelengths below 300 nm, other components of the solar spectrum, such as UVB and UVA, are of more concern. Although the UVA and UVB constitute a negligible portion of the sun's energy, they are primarily responsible for the pathological effects of solar radiation. For this reason, recent research has been directed more toward characterizing DNA damages produced by these biologically relevant solar wavelengths.

3 DNA Photoproducts

3.1 Pathways for Dissipating Absorbed Energy

Photon absorption rapidly converts a pyrimidine base to an excited state (Fig. 3). This event promotes an electron in a filled bonding π-orbital in the singlet ground state into a higher energy, empty π^* antibonding orbital, thus initiating photoproduct formation. Formation of an excited base occurs within 10^{-12} s after photon absorption. Various pathways are then available for resolution of this unstable electronic configuration. The major pathway involves rapid dissipation of the energy of the excited singlet base to the ground state (10^{-9} s) by nonradiative transition or by fluorescence, yielding heat or light in the process. Secondly, the excited base can react with other molecules to form unstable intermediates (i.e. free radicals) or stable photoproducts. Finally, there is a low probability that intersystem crossing, a nonradiative pathway, can transfer a base from the excited singlet state to the excited triplet state. The lifetime of the triplet state is several orders of magnitude longer than the excited singlet state (10^{-3} s), increasing the chance of photoproduct formation. Formation of the triplet state can be greatly enhanced in the presence of sensitizers such as acetone or acetophenone. The cyclobutane pyrimidine dimer (I in Fig. 4) forms through the excited triplet state, whereas, other photoproducts form by other mechanisms.

3.2 Types of DNA Photoproducts

The most abundant photoproduct induced by UVR is the cyclobutane pyrimidine

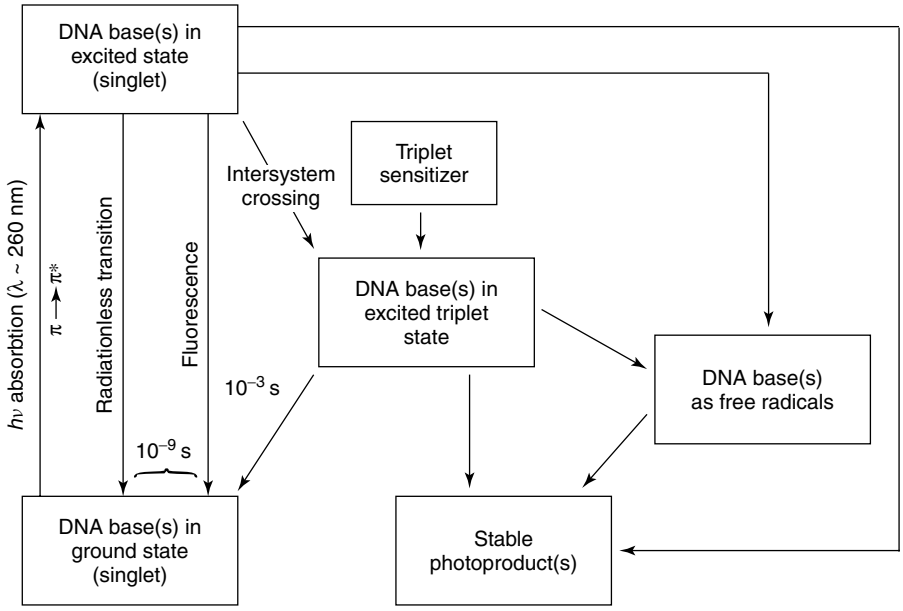

Fig. 3 Pathways of dissipation of energy absorbed by UVR. Schematic of the routes of UVR absorption and resolution leading to photoproduct formation.

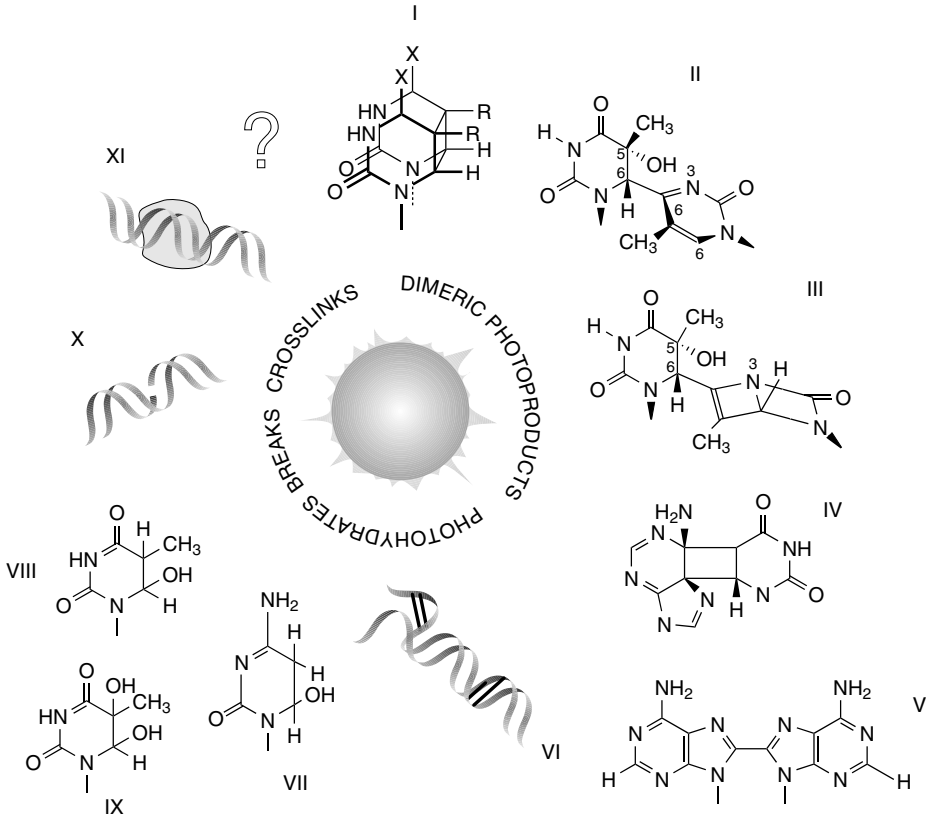

Fig. 4 DNA photoproducts. Types and structures of known photoproducts induced in DNA by solar UV radiation. I = CPD; II = (6-4)PD; III = Dewar pyrimidinone; IV = adenine–thymine dimer; V = 8,8 adenine dehydrodimer; VI = inter- and intrastrand DNA cross-links; VII = 6-hydroxy-5,6-dihydrocytosine; VIII = 6-hydroxy-5,6-dihydrothymine; IX = 5,6-dihydroxy-5,6-dihydrothymine (thymine glycol); X = single-strand break; XI = DNA-protein cross-link.

dimer or CPD (I) linked by a cyclobutyl ring between the 5 and 6 carbons of adjacent thymine (T) or cytosine (C) bases (Fig. 5). Of the four possible CPD combinations (T<>T, C<>T, T<>C, and C<>C), the T<>T dimer occurs with greatest frequency at 40 to 60% of the sum of cytosine-containing dimers. However, at wavelengths above 300 nm, the photochemical alterations of cytosine, rather than thymine, may account for most biological effects. The primary reason for this is that at wavelengths below 300 nm, saturation of CPD-containing cytosine occurs at a lower fluence and at a lower level than that of thymine homodimers (T<>T). Hence, whereas T<>T dimers form at a 1.5-fold *greater* frequency than dimers containing cytosine after UVC irradiation, they occur with one-third *less* frequency after UVB irradiation.

The pyrimidine(6-4)pyrimidone dimer or (6-4)PD (II) is the second most prevalent type of UV damage, occurring at 5 to

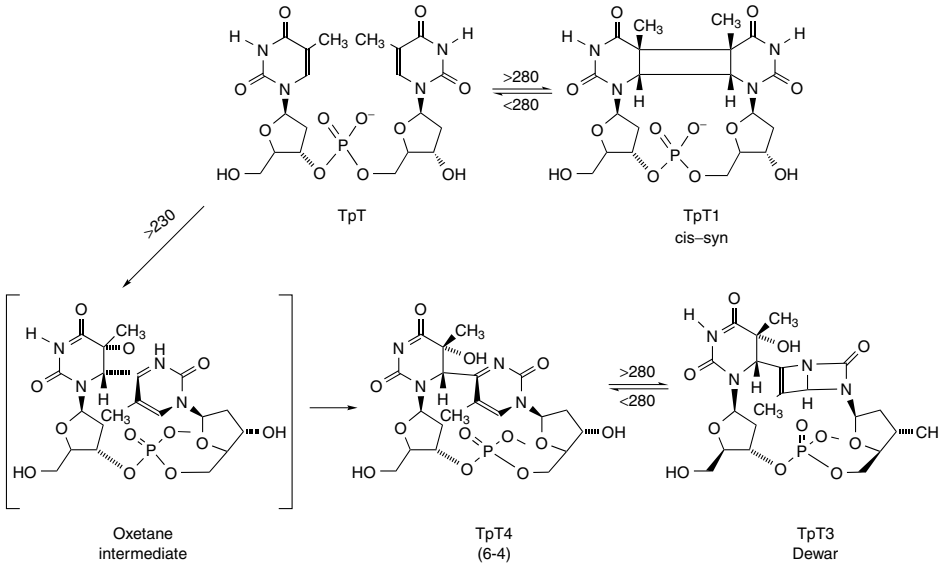

Fig. 5 Reaction scheme for the formation of the major UV photoproducts photochemical reactions in a dipyrimidine DNA sequence leading to the formation of the CPD (TpT1), (6-4)PD (TpT4), and Dewar pyrimidinone (TpT3). (Redrawn from Taylor and Cohrs, *J. Am. Chem. Soc.* **109**: 2834–2835 (1987), with permission).

50% of the frequency of the CPD. In this photoproduct, the 6 carbon of a 3′ pyrimidine (either cytosine or thymine) is linked to the 4 carbon of a 5′ pyrimidine (primarily cytosine) by way of an unstable oxetane or azetidine intermediate. Unlike CPDs, the formation of (6-4)PDs does not proceed via an excited triplet state (Fig. 3), hence is less dependent on the photochemical behavior of thymine bases in DNA. Infrared spectroscopic and nuclear magnetic resonance analyses of the (6-4)PD indicate that the plane of the 3′ cytosine base is shifted 90° relative to the 5′ thymine.

As shown in the reaction scheme for dimer formation (Fig. 5), absorption of UVB light by the (6-4)PD results in the formation of a structurally related photoisomer, the Dewar pyrimidinone (III in Fig. 4). Rare dimers containing purine, such as the thymine–adenine dimer (IV) and the 8,8-adenine dehydrodimer (V) have also been isolated from heavily irradiated DNA. Dimerizations between nonadjacent pyrimidines either on the same strand or on opposite strands can produce intra- or interstrand cross-links (VI). It should be kept in mind that the relationship between photoproduct frequency and its biological effect depends on the intrinsic capability of that lesion to kill cells or to induce mutations. Hence, even though a photoproduct may occur at a very low frequency, its structure and location may elicit a potent biological effect.

Compared with photoproducts involving two pyrimidines, those involving a single base occur in DNA at very low frequencies (≈1–2% of dimers) after exposure to UVR. Because of its instability, the photobiology of the cytosine photohydrate (VII) has been

difficult to study using the conventional analytical procedures for quantifying DNA damage. It should be kept in mind, however, that the half-life of the cytosine photohydrate is not trivial (i.e. 24 h at room temperature) and this lesion may indeed pose a viable biological threat to a proliferating cell system. Recent data using sequencing analysis indicate that saturated thymine photoproducts (VIII and IX), such as the thymine glycol, do not occur in UVC- or UVB-irradiated DNA at a significant rate, hence, they do not appear to contribute significantly to the biological effects of UVR.

In contrast with the induction of DNA damage resulting from the direct absorption of UVC light, UVA and UVB may produce damage indirectly through highly reactive chemical intermediates. Similar to ionizing radiation, these wavelengths generate reactive oxygen species (ROS) that can form, for example, singlet oxygen, hydroxyl and peroxyl radicals, and superoxide anions which in turn can react with DNA to form single base damage, such as 8-oxodeoxyguanosine, as well as strand breaks and DNA-protein cross-links (X and XI in Fig. 4). Although the number of cytosine photohydrates compared to CPDs and (6–4)PDs remains constant throughout the UVR, the relative proportion of single-strand breaks and protein DNA cross-links increases significantly in DNA irradiated with UVB and UVA light.

3.3 DNA Photoproduct Distribution

A major pathway of cell killing by UVR results from DNA damage that inhibits DNA synthesis or transcription of genes essential to cell growth and metabolism. Recent advances in biotechnology have greatly increased our understanding of the diverse nature of DNA damage in mammalian systems, particularly regarding the spatial and temporal distribution of UV photoproducts in mammalian chromatin. Photochemical and biochemical data indicate that the distribution of UVR damage is nonrandom, determined by DNA sequence and DNA–protein interactions.

Using biochemical and immunological techniques, (6-4)PDs were quantified at approximately 23% of the level of CPDs in purified DNA irradiated *in vitro*. However, the relative occurrence of (6-4)PDs and CPDs varies widely, depending on base content of DNA, state of methylation, and chromatin structure. For example, the ratio of CPDs and (6-4)PDs correlates with the AT : GC ratio with CPDs occurring in *Clostridium perfringens* DNA (30% AT : GC) > *Escherichia coli* DNA (50% AT : GC) > *Micrococcus luteus* DNA (70% AT : GC). Using DNA sequencing techniques, the incidence of (6-4)PDs and CPDs in fragments of the *lacI* and *supF* genes is highly variable and sequence-dependent. Specifically, CPDs occur predominantly at T–T, less frequently at T–C and C–T, and least often at C–C sites. In contrast, (6-4)PDs can occur with 100-fold greater frequency than CPDs at certain dipyrimidine sites. Specifically, (6-4)PDs form predominantly at T–C, less frequently at T–T and C–C and rarely at C–T sites. Cytosine methylation significantly increased the yield of (6-4)PDs after exposure to UVC and of CPDs and (6-4)PDs after exposure to UVB. Hence, both types of dimers are preferentially induced at 5-methylcytosine bases in DNA of cells exposed to solar UVR.

The distribution of UV photoproducts is influenced by secondary structure mediated through DNA–protein interactions; namely, chromatin structure modulates sites of CPD induction in core nucleosome

DNA. Using the 3′–5′ exonuclease activity of T4 DNA polymerase to map UV photoproducts, it was shown that they do not occur randomly along the DNA helix, but are situated with a periodicity of 10.3 bases. Sites of maximum photoproduct induction in core DNA correspond to sites in which the phosphate backbone is farthest from the core histone surface. The limited flexibility of the DNA helix resulting from histone–DNA interactions is thought to inhibit photoproduct formation.

The relative induction of (6-4)PDs and CPDs has been measured in nucleosome (core) and internucleosome (linker) DNA in UV-irradiated human chromatin. CPDs form in equal amounts per nucleotide in core and linker DNA, whereas (6-4)PDs occur with sixfold greater frequency per nucleotide in linker DNA. These data indicate that (6-4)PD formation is strongly influenced by DNA–protein interactions, occurring more readily in DNA that is less tightly bound to nucleosomal proteins. These studies suggest that (6-4)PDs may be more readily induced in actively transcribing genes compared to quiescent genes or in the overall genome in human fibroblasts. Preferential induction of (6-4)PDs in functionally active regions of chromatin would serve to increase the lethal potential of this type of photodamage. Indeed, repair of these lesions (see below) may be facilitated by their predominance in nonnucleosomal (metabolically active) regions of the genome; DNA damage in more open chromatin conformations (CC) may be more accessible to excision repair enzymes compared to damage induced in more compact regions.

Mutagenicity of UV photoproducts and low fidelity DNA polymerases The progression of replicative class B polymerases, including Pol A, D, and E are blocked by most types of photoproducts. Depending on their structures, many photoproducts are, however, bypassed during DNA replication to different degrees by damage-specific class-Y DNA polymerases including Pol H, I, and K that have low fidelities due to expanded active sites that facilitate read-through of noninformative sequence information (e.g. abasic sites). Pol H has the greatest capacity to replicate a large variety of DNA lesions and preferentially inserts adenine in the nascent strand opposite the lesion (called the *A rule*). Pol I preferentially inserts guanine and is capable of replicating C-containing photoproducts. Pol H or I, therefore, can insert bases opposite dipyrimidine photoproducts, but the 3′ complementary base will be mismatched either by an erroneous insertion or the distortion caused by the photoproduct. The absence of Pol H results in increased mutagenesis and has the most recognizable pathological consequence in the human disease Xeroderma pigmentosum variant complementation group.

This mechanism has two important implications regarding the mutagenicity of different photoproducts. First, mutations will most often occur where cytosine is a component of the photoproduct since insertion of adenine opposite thymine is a correct and nonmutagenic event. Hence, most CPDs, because they form between two thymine bases, are not mutagenic. Second, the more distortive a lesion is, the more likely it will block DNA synthesis and will result in a lethal rather than a mutagenic event. Since the (6-4)PD is considerably more distortive than the CPD (i.e. it causes a 47° as opposed to a 7° helical bend) it is more likely to be lethal rather than mutagenic. Because damage bypass and base insertion depend on a

variety of conditions, both CPDs and (6-4)PDs contribute to tumorigenesis in a complex manner.

The role of specific photoproducts in UV mutagenesis in human cells has been investigated with the use of shuttle vectors. In these systems, UV-irradiated simian virus SV40-based plasmids are transfected into mammalian host cells (e.g. mouse and human) where they are replicated. The plasmids are subsequently recovered, amplified in bacteria, and analyzed for mutations by DNA sequencing. Sites of mutations can then be compared with sites of photoproduct induction in the target sequence. Results of these studies indicate that sites of transition mutations correlate with sites of increased (6-4)PD induction (Table 1). In the *supF* gene inserted into the mouse L-cell chromosome and in the endogenous *APRT* gene of Chinese hamster ovary (CHO) cells, most of the mutations consisted of C→T transitions occurring at T–C and C–C sequences. Owing to the strand-specificity of repair (see below), a bias was observed between mutations in the coding and the noncoding strands of expressed genes that differed according to the repair capacity of the cells.

Because CPDs and (6-4)PDs can both form at sequences shown to be mutation hotspots in shuttle vectors, the identity of the mutagenic lesion was also tested by photoenzymatic repair (PER) (see below) of the *supF* sequence in plasmids prior to transfection. Specific photoreversal of CPDs reduced the mutation frequency in normal cells by 75% and in XP group A cells by 90%. These results are not consistent with the model developed in *E. coli* and suggest that (6-4)PDs may be less mutagenic in human cells. A comparison of photoproduct yields, rates of repair, and mutations in the *PGKI* and p53 genes,

Tab. 1 UVC-induced mutations observed in shuttle vector pZ189 replicated in XP or normal human cells.

Mutations	***Number of plasmids with base changes***	
	XP	***Normal***
Independent plasmids sequenced	61 (100%)	89 (100%)
Point mutations		
Single base substitution	47 (77%)	48 (53%)
Tandem base substitutions	12 (20%)	16 (18%)
Multiple base substitutions	1 (2%)	24 (28%)
Base insertions and deletions		
Single base insertion	0	2
Single or tandem base deletions	1	3
Types of single or tandem base substitutions and number of changes		
Transitions	67 (94%)	61 (75%)
GC to AT	66 (93%)	59 (73%)
AT to GC	1 (1%)	2 (2%)
Transversions	4[d] (6%)	20 (25%)
GC to TA	0[d]	8 (10%)
GC to CG	1 (1%)	5 (6%)
AT to TA	3 (4%)	6 (8%)
AT to CG	0	1 (1%)

however, has shown that regions of high UV-induced mutation can be caused by either or both high photoproduct yield and low repair. A combination of initial yields and rates of repair that leave a high net-persistent load of photoproducts in a particular site appear to be directly related to the mutational yield. Using ligation-mediated polymerase chain reaction (LMPCR) that allows precise location of damaged bases, the photoproduct distribution in exons 1 and 2 of three *ras* proto-oncogenes was mapped and no correlation between photoproduct frequency and mutation induction in codon 12 of H-*ras* and K-*ras* was found. DNA repair at individual nucleotides in the p53 tumor suppressor gene was highly variable and sequence-dependent with slow repair observed at seven of the eight positions associated with mutations. UV-induced mutations in the p53 gene are a probable step in the formation of squamous cell carcinoma (SCC) and may arise at DNA repair ''coldspots'' rather than photoproduct ''hotspots.''

4
Analytical Techniques

4.1
Detecting and Quantifying DNA Photoproducts

Methods for quantifying photoproducts in DNA rely on (1) separation of modified bases by chromatography, (2) enzymatic or biochemical incision of DNA at sites of photoproducts, or (3) antibody binding to structural damage in DNA (Table 2). Damage caused by UVR was first detected in DNA nearly 40 years ago using paper chromatography. Chromatographic measurements require that DNA photoproducts either be labeled during cell proliferation by incorporation of a radioactive pyrimidine precursor, such as [^{3}H]-thymidine, or postlabeled using [$\delta-^{32}$P] ATP after enzymatic hydrolysis. After UV-irradiation, the DNA is extracted, purified, and reduced to individual bases by acid or enzymatic hydrolysis. Photoproducts are then separated from unmodified bases by two-dimensional paper, thin-layer, or high-performance liquid chromatography (HPLC). A standard procedure for quantifying 8-oxodeoxyguanosine residues in DNA after hydrolysis is HPLC combined with electrochemical detection of the lesion (HPLC-EC).

Enzymatic or chemical incision of DNA at sites of damage and subsequent quantification of the resultant single-strand breaks by various means can also be used to measure UV photoproducts. Sites of CPDs can be cleaved with UV endonuclease V from T4 phage, an enzyme that specifically recognizes this type of damage. UvrABC exinuclease, a partial excision repair complex purified from *E. coli*, and an ultraviolet damage endonuclease (UVDE) purified from yeast, cleave DNA at or a few bases to either side of CPDs or (6-4)PDs in DNA. Both broad-spectrum enzymes have been used to measure overall levels of DNA damage in UV-irradiated DNA and nondimer damage remaining after the removal of CPDs or (6-4)PDs by enzymatic photoreactivation. Other enzymes involved in base excision repair (BER) have been used to cleave DNA at sites of nondimer photodamage, including endonuclease III (nth protein) and formamidopyrimidine glycosylases (fpg protein) purified from *E. coli* as well as a human endonuclease that specifically cleaves 8-oxodeoxyguanosine residues in DNA (hOGG). Such enzymes have been used to cleave DNA at cytosine and thymine photohydrates, fragmented

bases and sugars, photo-oxidation products, as well as unidentified photoproducts occurring at sites of (6-4)PDs and modified purines.

Several analytical techniques have been developed around the ability to specifically break DNA at sites of photoproducts. A single-strand nick at the site of a lesion in a supercoiled molecule converts that molecule from its compact supercoiled form to a relaxed form that can be easily resolved and quantified using gel electrophoresis. Other techniques required separation of the DNA strands and molecular weight determinations of the resultant single-strand fragments. Alkaline sucrose gradient sedimentation, denaturing gel electrophoresis, and microcapillary electrophoresis are approaches used to quantify endonuclease digestion at sites of UV damage. As with the chromatographic techniques, analyses of photodamage as strand breaks require radioactive or fluorimetric labeling to visualize and quantify DNA. A variation on this approach has combined alkaline gel electrophoresis with Southern blotting to detect and quantify strand-break frequencies in specific DNA sequences (genes) and has led to the discovery and description of transcription-coupled repair (TCR) (see below). Gene-specific repair

is also possible using quantitative PCR in which the ability of DNA photoproducts or strand breaks produced at sites of DNA photoproducts to block the progression of Taq polymerase is exploited. A further refinement of this technique combined with PCR technology has led to the development of ligation-mediated PCR (LMPCR) and the analysis of DNA damage at base resolution in cellular DNA. Previously, the sequence-specificity of photoproduct induction was limited to *in vitro* analyses using Maxam–Gilbert sequencing. Although all of these techniques are more sensitive than chromatography, their sensitivity depends on the maintenance of high-molecular weight DNAs throughout the purification and analysis.

Over the past 20 years, antisera raised against UV-irradiated DNA have proven to be powerful and versatile reagents for the study of various photochemical and photobiological phenomena. Polyclonal and monoclonal antibodies have been produced, which bind a variety of photodamage, including the CPD, (6-4)PD, Dewar pyrimidinone, and thymine glycol. A variety of immunological assays have been developed and have provided unique insights into photochemical and photobiological problems. Prominent within the extensive arsenal of immunological approaches adapted to the analysis of DNA damage and repair is immunoprecipitation of radiolabeled DNA fragments, enzyme-linked immunosorbent assays (ELISA), radioimmunoassays (RIA), immunoslot blots, and immunodot blots. The first and last of these techniques measure direct binding of antibody to damaged DNA; ELISA and RIA are competitive binding assays with considerably greater sensitivity and flexibility. A technique has even been developed in which CPDs were visualized in DNA using electron microscopy. Each technique has its own unique attributes and applications. Unlike chromatographic techniques, immunological assays do not require chemical or enzymatic degradation of DNA prior to analysis; unlike endonucleolytic assays, their sensitivities do not depend on the molecular weight (or purity) of sample DNA.

Many of the approaches discussed above can be adapted to the analysis of UV photoproducts in single cells, thereby greatly increasing the sensitivity of the assay. Strand breaks associated with DNA damage have been visualized in single cells using the ''Comet assay'' in which cells are embedded in agarose and the DNA extruded from the nuclei in an electric field. The resultant image, visualized with fluorescent dyes, resembles a comet with the head of the comet representing the nucleus and tail, the extruded DNA. The length and quantity of DNA in the tail is used to quantify the number of strand breaks and, hence, the amount of DNA damage. Antibodies to UV photoproducts have also been applied to CPD and (6-4)PD analyses in individual mammalian and bacterial cells. Secondary antibodies tagged with a fluorescent dye (e.g. fluorescein) bind to the primary damage-specific antibodies and allow visualization and quantification of the signal using fluorescence microscopy and image analysis software.

4.2 Quantifying DNA Repair

Removal of individual photoproducts can be assayed directly using the techniques described above. Techniques have also been developed to monitor various stages of the excision repair process. Transient incisions associated with the initial step of excision repair (Figs. 7 and 8) can be measured using alkaline elution. Alkaline

lysis of cells on filters results in denaturation of the DNA, which then elutes at a rate dependent on its molecular weight. Smaller DNA fragments containing more incisions elute faster than larger fragments; by measuring the molecular weight of the eluting fragments, the rate of repair incision can be estimated. Incorporation of base analogs (e.g. 1-ß-D-arabinofuranosylcytosine), which result in premature termination of repair synthesis, cause strand break accumulation. To discriminate between strand breaks associated with DNA repair and DNA replication, semiconservative DNA synthesis can be inhibited by specific inhibitors (e.g. hydroxyurea) or nonreplicating senescent (G_0) or terminally differentiated nonproliferating cell populations can be used. Studies with normally UV-resistant mammalian cells show a rapid accumulation of strand breaks within the first few (0–15) minutes after UV-irradiation followed by gradual restoration to the original molecular weight within an hour. The Comet assay has also been used to estimate the extent of incision associated with DNA repair.

As with incision assays, protocols for measuring the resynthesis stage of excision repair must utilize cells in which normal DNA replication has been inhibited. Unscheduled DNA synthesis (UDS) provided the first direct evidence for the DNA excision repair process in mammalian cells. Cells were grown for a short period (pulsed) in [^{3}H]-thymidine and then examined autoradiographically (as silver grains on a photographic plate). Cells undergoing DNA synthesis displayed intense labeling of their nuclei, whereas nonreplicating cells undergoing repair (unscheduled) synthesis showed much reduced labeling. Repair synthesis can also be determined using buoyant density centrifugation of DNA. In this technique, the base analog 5-bromodeoxyuridine (BUdR) is incorporated into DNA in place of thymidine. Regions containing this base have a higher density than the surrounding DNA. Hence, DNA that has replicated semiconservatively (i.e. produced one entire new strand) migrates as a hybrid density band on cesium chloride gradients. Repair synthesis occurring in very small patches ($\approx$30 bases) migrates to a position of normal density DNA. The amount of radioactivity [(^{3}H)-labeled BUdR] incorporated into unreplicated DNA is a measure of the total amount of repair synthesis.

The DNA repair capacity of a cell can also be determined using transient expression assays. Several of these assays have been developed, each varying only in the ''reporter'' gene utilized. In this assay, a plasmid containing a gene that can be expressed in a specific host cell is UV-irradiated and transfected into a host cell using one of a variety of transfection protocols. The ability of this gene to recover expression of a certain product (e.g. chloramphenicol acetyl transferase, β-galactosidase, luciferase) reflects the ability of the cell to repair the DNA damage induced in that sequence. Transient expression assays thus measure gene-specific repair.

5 DNA Damage Tolerance Mechanisms

The amount of photodamage present in cellular DNA at any given time depends not only on the extent of UV light absorbed by the DNA but also on the ability of the organism to repair the damage. UV damage tolerance mechanisms vary and may include combinations of photoprotection and DNA repair. The DNA repair strategy

utilized depends on the type of photoproduct encountered and the organism at risk. DNA repair is composed, in whole or part, of at least two well-studied mechanisms, photoenzymatic repair and nucleotide or base excision repair (Figs. 6–8).

5.1 Photoprotection

Nearly all organisms have behaviors or natural features that lower exposure of DNA to solar UVR and reduce the amount of photodamage. Human behavior includes wearing clothes, hats, sunglasses, and sunscreens, and general occupational and recreational life-styles. Many plants and animals have similar strategies. Biological components such as bark, cuticles, skin, fur, feathers, scales, and shells can strongly attenuate or eliminate the absorption of UVR by internal areas of cells or organisms. Habitat selection is also a significant factor. Shielding by terrain, foliage, water, or another organism can reduce UVR exposure. Actively seeking shade to avoid direct sunlight is also a common biological response.

Morphology may also affect the amount of radiation absorbed by cellular DNA. Small cells and organisms are more susceptible to the physical damage caused by ionizing radiation. Recent studies on marine plankton indicate that UVR damage may likewise be mediated by morphological factors. The amount of DNA damage induced in phytoplankton and bacterioplankton by UVB light correlates with the size of the individual species. In smaller cells, the distance between the cell surface and nuclear DNA is less than in larger cells. The shortened light path reduces refraction and absorption by cytoplasmic components and increases the amount of UVR reaching the nucleus. Similar principles can be applied to multicellular organisms. In humans, for example, the ratio of exposed surface area to internal tissues and organs is reduced when compared to smaller animals.

Several mechanisms for biochemical protection from UVR occur in nature. Pigmentation in the outer layers of plants and animals modulates the intensity and wavelength distribution of light reaching internal components. In some cases, light exposure induces pigment production. For example, the UVR absorbing compounds melanin and anthocyanin are produced in human skin and plants respectively, after exposure to solar UV. Melanin has multiple functions that can be either harmful or beneficial to the organism. On the one hand, it can be photoprotective, acting as a natural sunscreen, although not a very good one, and as a scavenger of active chemical species produced by solar UVR, although again not a very effective one. On the other hand, melanin can itself produce active radical species that can damage DNA and has the capacity to bind to drugs in ways that can either benefit or harm the cell. The beneficial role of melanin in humans is best illustrated by the observed reduction in skin cancers such as basal and squamous cell carcinomas and protection against sunburn in dark-skinned peoples. In black skin, melanosomes, the cellular compartments in which melanin is sequestered, are oval, single, and densely packed with melanin and clustered around the nucleus. UVR is blocked from the nucleus and free radicals are absorbed. In contrast, in white skin, melanosomes are round, aggregated, and lightly melanotic. UVR can bypass the clusters to enter the nucleus.

In addition to pigments, colorless UV-absorbing compounds have also been identified as possible UV-protective chemicals.

Concentrations of flavenoids in terrestrial plants, mycosporine amino acids (MAAs) in fungi, and mycosporine-like compounds in marine organisms all correlate with UV exposure history. Over 25 different mycosporine-like compounds have been identified in marine algae and invertebrates. These molecules display different UVA and UVB absorption profiles, with several compounds present in a single species. Combinations of these ''natural sunscreens'' provide broadband UV coverage and optimize protection from solar UVR. Because of these attributes, these compounds are being investigated for human applications.

5.2 Photoenzymatic Repair

Photoenzymatic repair is a light-dependent process involving the enzyme-catalyzed reversal of CPDs (Fig. 6). This was the first DNA repair mechanism recognized, discovered simultaneously by Albert Kelner and Renato Dulbecco in 1949. PER involves binding of a low molecular weight protein to a CPD followed by absorption of photons within the UVA/visible range of light, reversal of the damage, and, finally, release of the enzyme. PER appears to be a ubiquitous repair mechanism widespread throughout the plant and animal kingdoms (Table 3).

Although it is a relatively simple enzymatic process, PER displays much diversity in various biological systems. There are numerous organisms in which it has not been found, including several bacteria, such as *Haemophilus influenzae*, *Diplococcus pneumoniae*, *Bacillus subtilis*, and *Micrococcus radiodurans*, some algae and higher plants, such as *Chaetoceros convolutus*, *Thalassiosira australis*, *Phaseolus aureus* and *Haplopappus gracilis*, the nematode, *Caenorhabditis elegans*, and in placental, but not marsupial, mammals. Differences in action spectra, constitutive levels of photolyase, and the presence of required cofactors may account for the diverse PER efficiencies among organisms. The wavelength dependence for maximum PER efficiency is ≈380 nm in *E. coli* and *Euglena*, ≈400 nm in *Neurospora*, and ≈440 nm in *S. griseus*. The lack of PER in many organisms and its evolutionary conservation in systems never exposed to sunlight (e.g. soil or enteric bacteria, Blind cave fish)

Tab. 3 Plants and animals capable of removing cyclobutane dimers by enzymatic photoreactivation (PER).

Group	***Species***	***Common name***
Cyanobacteria	*Plectonema boreanum*	Blue-green alga
	Anacystis nidulans	Blue-green alga
Schizomycophyta	*Escherichia coli*	Colon bacteria
	Streptomyces griseus	Soil actinomycete
Eumycophyta	*Saccharomyces cerevisiae*	Baker's yeast
	Neurospora crassa	Bread mold
Euglenophyta	*Euglena gracilis*	[a]
Angiospermae	*Phaseolus vulgaris*	Pinto bean
	Phaseolus lunatus	Lima bean
	Arabidopsis thaliana	[a]
	Zea mays	Maize
	Nicotiana tabacum	Tobacco
Gymnospermae	*Gingko biloba*	Gingko tree
Protozoa	*Paramecium Aurelia*	Paramecium
	Tetrahymena pyriformis	[a]
Mollusca	*Physa sp.*	Pond snail
Echinodermata	*Arabacia punctulata*	Sea urchin
	Echinarachnius parma	Sand dollar
Arthropoda	*Angasta Kiihniella*	Flower moth
	Gecarcinus lateralis	Land crab
	Artemia salina	Brine shrimp
	Homarus americanus	Lobster
Insecta	*Trichoplusia ni*	Cabbage looper
	Drosophila melanogaster	Fruit fly
Teleosts	*Haemulon sciuris*	Blue-striped grunt
	Pimephales promelas	Fathead minnow
	Anoptichthys jordani	Blind cave fish
	Tautoga onitis	Tautog
	Tautogolabrus adsperus	Cunner
	Xiphopherus variatus	Variable platyfish
	Carassius auratus	Goldfish
Amphibia	*Bufo marinus*	Cowflop toad
	Xenopus laevis	African Clawed toad
	Rana pipiens	Leopard frog
Reptilia	*Terrapene Carolina*	Box turtle
	Iguana iguana	Iguana lizard
	Gekko gekko	Gecko lizard
Aves	*Gallus gallus*	Domestic chicken
Marsupialia	*Didelphis marsupialis*	American opossum
	Caluromys derbianus	Woolly opossum
	Potorous tridactylis	Rat kangaroo
Mammalia	(*Homo sapiens?*)	Human

[a] No common name.

suggests photolyase may function in other molecular processes, such as excision repair. In support of this idea, it has been shown that *E. coli* photolyase stimulates excision repair *in vitro* and a DNA-binding protein associated with excision repair in human cells (XPE protein) has been identified with properties similar to a yeast photolyase. It has been shown that PER is inducible in fish cells, both in culture and *in vivo* (in caudal fins). Preillumination with visible light 8 h prior to damage induction significantly predisposes cells to CPD removal by PER. These studies provided the first clear demonstration of an inducible repair system in eukaryotes

Photoenzymatic repair of (6-4)PDs has also been observed in many organisms including insects (*Bombyx mori* and *D. melanogaster*), reptiles (*Crotalus atrox*), amphibia (*X. laevis*), and fish (*Xiphophorus* spp.). The (6-4)PD but not its Dewar isomer is the substrate for these photolyases and the enzyme has an average action spectrum peak at 400 nm. The efficiency of repair per incident photon is very low compared with CPD photolyases, and it appears that the (6-4)PD photolyase converts the photoproduct to unmodified bases, probably through an oxetane intermediate.

5.3 Excision Repair

DNA excision repair is a genetically complex and phenotypically diverse system; its competency is dependent on the species and developmental state of the individual as well as on the type of photoproduct encountered and its genomic distribution. The excision repair pathway is thought to proceed by the following fundamental steps: (1) recognition of the lesion as a structural distortion in the DNA helix; (2) unwinding or other activity to disassociate the lesion from chromatin proteins and provide accessibility to repair enzymes; (3) incision of the DNA backbone at or near the site of the lesion; excision and resynthesis of the DNA around the damaged site; and (4) ligation of the single-strand nick remaining after disengagement of the DNA polymerase complex. This process is very versatile, correcting various classes of chemical damage in addition to those induced by UVR.

5.3.1 Excision Repair Pathways

Excision repair may proceed by one of two routes (Figs. 7 and 8). Base excision repair (BER) is initiated by enzymatic recognition of the lesion and scission of the bond between the damaged base and its associated deoxyribose sugar, a process called aglycosylation. BER-initiating enzymes fall into two distinct categories: the hydrolytic dRPases and AP lyases. Examples of AP lyases include (1) endonuclease III which repairs several types of base damage including pyrimidine photohydrates, (2) pyrimidine dimer glycosylases from T4 phage-infected *E. coli* and *M. luteus*, which have the unique capability to recognize the 5′ pyrimidine of a CPD as a modified base, and (3) FaPy-DNA glycosylase from *E. coli*, which recognizes and cleaves various types of radiation damage including 8-oxodeoxyguanosine. After removal of the base damage, a 3′ AP lyase or 5′ AP endonuclease cleaves the phosphodiester bond adjacent to the abasic site. Enzymes that release 5′-deoxyribose-5-phosphate (dRP) residues from preincised AP-DNA have been collectively termed DNA-deoxyribophosphodiesterases (dRPases). To prepare the strand for resynthesis, the 3′ diesterase activity associated with AP lyase or the 3′–5′ exonuclease activity associated with dRPase and pol β digests

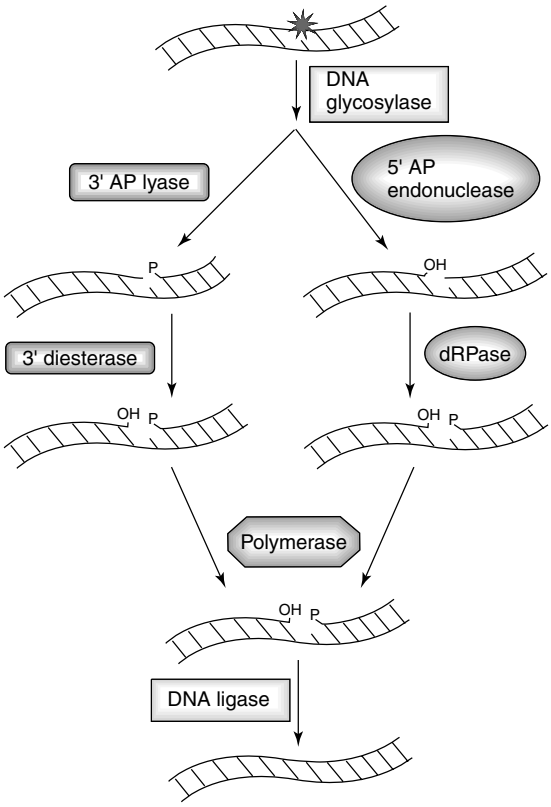

Fig. 7 Base excision repair. Pathway for generalized BER is shown including DNA damage cleavage by glycosylases, damage removal by endonuclease digestion, and gap-filling by DNA polymerase and DNA ligase.

the remaining abasic site. The damaged strand is removed and resynthesized in *E. coli* by pol I and in mammalian cells by pol β and the XRCC 1 gene product. The remaining nick is repaired by DNA ligase returning the DNA duplex to its original state. In addition to the short-patch repair described, BER may also proceed by a long-patch repair mechanism in which 2–13 new bases are inserted. The primary difference between short- and long-patch repair is the utilization of different polymerases and flap endonuclease (Fen1) for excision and resynthesis.

The nucleotide excision repair (NER) pathway recognizes a broad spectrum of UVR-induced photoproducts as well as other ''bulky adducts'' that may be induced by genotoxic agents. This process has been well studied in *E. coli* and is thought to be the primary excision repair pathway in eukaryotes as well. As with BER, enzymes that recognize and bind the helical distortion created at the damaged site initiate the NER process. In prokaryotes, a fairly simple multiprotein complex consisting of the Uvr A, B, C, and D scans the DNA for helical distortions, assembles at the lesion site, cleaves the DNA on both sides of the lesion leaving a gap, and is displaced to repeat the process. A DNA polymerase fills the gap and the strand is ligated to restore the DNA duplex to its original integrity.

In eukaryotes, NER is the most important repair process concerned with UVR

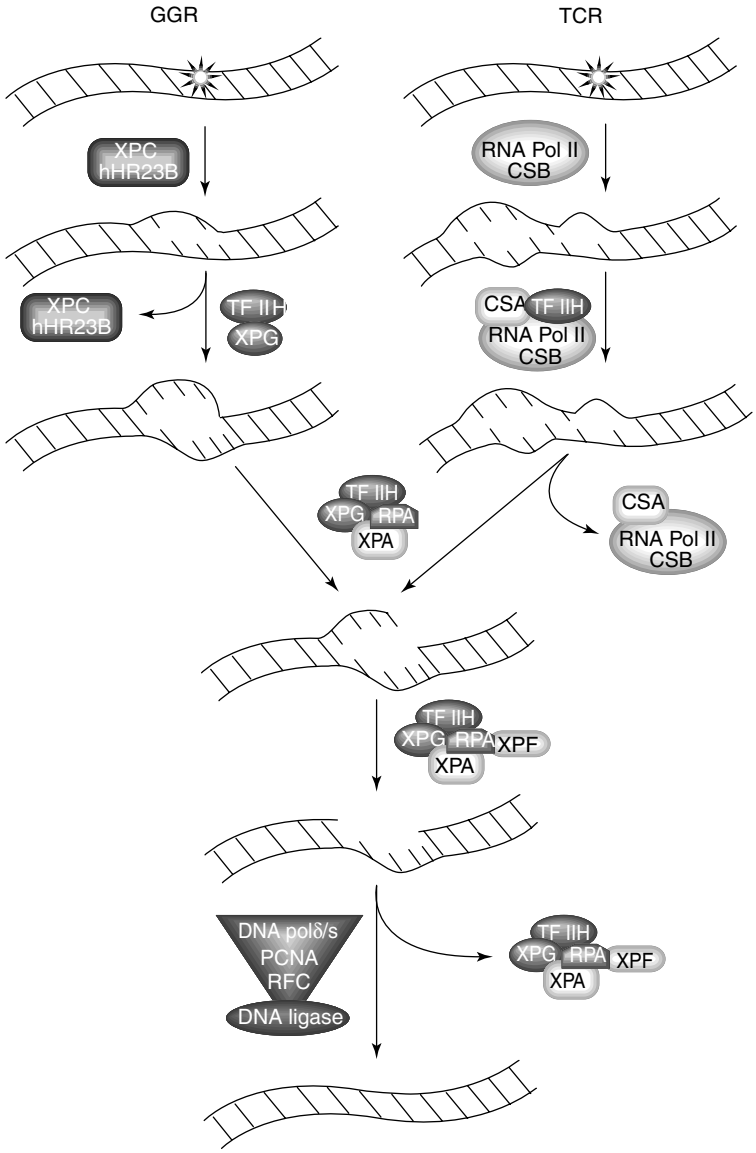

Fig. 8 Nucleotide excision repair. Generalized pathways for global genome (GGR) and transcription-coupled repair (TCR) in eukaryotes. Enzymes, DNA damage–binding proteins, and complexes are shown for DNA-damage recognition, stabilization, incision, excision, and resynthesis.

damage. Two major pathways of NER are known: transcription-coupled repair (TCR) and global genome repair (GGR) (Fig. 8). These NER pathways remove CPDs and (6-4)PDs in DNA and replace the damaged site with a newly synthesized polynucleotide patch approximately 29 bases in length. TCR removes damage more rapidly

from the transcribed strands of transcriptionally active genes, whereas GGR acts more slowly on nontranscribed regions and is regulated by p53 through control of XPE p48 expression. An increased excision rate in active genes (TCR) may also occur for (6-4)PDs, but this is less easily resolved against the greater overall rate of excision of these photoproducts in the genome as a whole. The differences in excision from active versus inactive genes occurs because a basal transcription factor, TFIIH, regulates basal transcription by RNA polymerase II and plays a major role in repair (Fig. 8). A detailed study of the promoter and first exons of the *PGKI* gene has indicated that excision is slow in regions of promoter binding but increases immediately after the transcription start site.

Many of the genes that regulate TCR are associated with the human disorders Xeroderma pigmentosum (XP), Cockayne syndrome (CS), trichothiodystrophy (TTD), and other disorders (see Sect. 5.3.3). Two of the helicases in TFIIH correspond to the *XPB* and *XPD* genes, and others are known to play a role from their analogs in the yeast transcription factor B. TCR also involves the CS genes *CSA* & *CSB, XPG*, the mismatch repair gene *MLH2*, and the breast cancer susceptibility gene *BRCA1*.

In Fig. 9, excision repair of damaged sites in mammalian chromatin is shown. The first step involves mechanisms that recognize damage and dissociate nucleoproteins to make the DNA accessible to repair enzymes. After recognition and dissociation, the excision repair pathway proceeds as in Fig. 8, followed by reassembly and repackaging of the chromatin complex. The actual number of damaged sites involved in excision repair at any one time is very small, comprising only about 1% of the lesions produced in DNA irradiated with a low UV fluence. Excision is, therefore, rate-limited by the enzymes involved in the early stages of DNA repair which dissociate the DNA from the nucleosome scaffolding and provide accessibility to excision enzymes.

5.3.2 Temporal and Spatial Distribution of Excision Repair

The efficiency of the excision repair process is dependent on the organism, the type of damage encountered, and where it occurs in the genome. In Fig. 10, repair curves for CPD and (6–4)PD excision are shown for several organisms representing the plant and animal kingdoms. The initial rates and extent of CPD repair (Fig. 10(a)) show great diversity, ranging from very rapid removal in primitive eukaryotes, such as bread mold and yeast, to much slower repair in vertebrates such as fish, frogs, and mammals. With few exceptions, the rate of (6-4)PD excision is much faster than the CPD (Fig. 10(b)). Notable exceptions include the common bread mold (*N. crassa*), the nematode *C. elegans*, and the epidermis of the marsupial *Monodelphis domestica*. Rapid repair of the (6-4)PD may be a consequence of its structure and its nonrandom distribution in chromatin. The 90° orientation of the 3′ base of the (6-4)PD (Fig. 4) produces a segment of DNA with considerable distortion in the phosphodiester backbone, local denaturation, and disruption of normal base pairing. This structure is bound with 10-fold greater affinity by the UvrABC exinuclease of *E. coli* and blocks the progression of DNA polymerase about 20-fold more efficiently than the CPD.

Rapid repair of the (6-4)PD may also belie the structural and functional role of chromatin in DNA repair (Fig. 9). Insight into the relationship between DNA repair and chromatin structure has come from studies using a yeast minichromosome

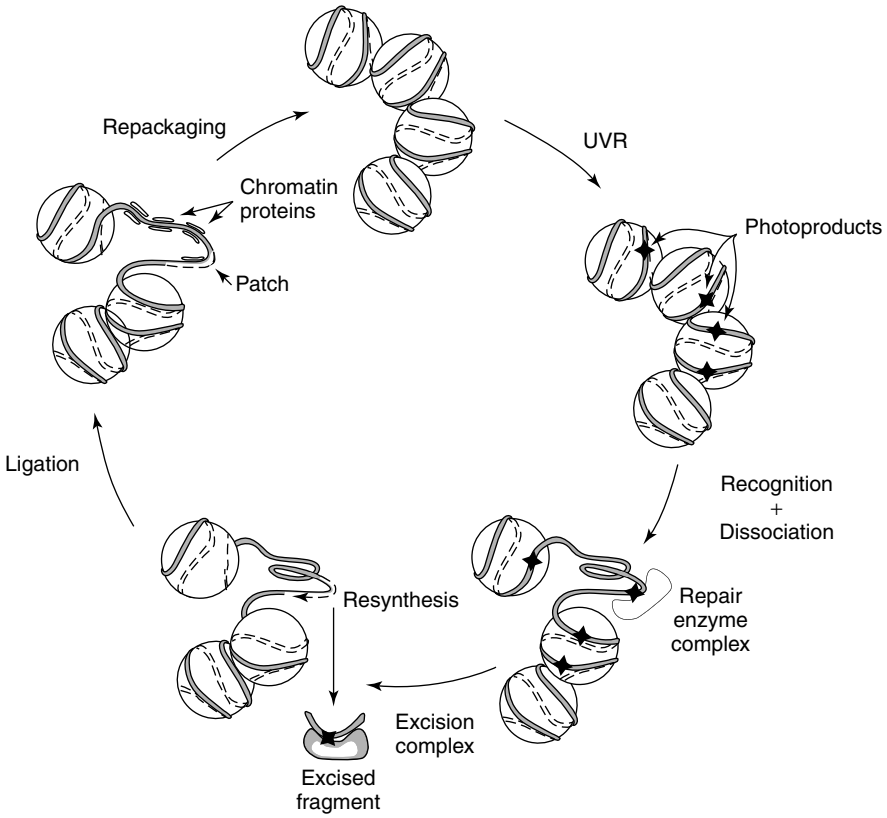

Fig. 9 Excision repair in mammalian chromatin. Repair is initiated by photoproduct recognition and dissociation of damaged DNA from nucleoproteins to make the DNA more accessible to repair enzymes. This is followed by the sequential incision by an endonuclease, excision, and resynthesis by a DNA polymerase, and sealing of the patch by a polynucleotide ligase. The repaired segment is finally reassembled and repackaged in the original nucleosomal structure. (Redrawn from Cleaver and Mitchell, 1993).

as a model system. Regions of this chromosome containing unstable nucleosomes are more readily repaired than regions in which the nucleoprotein structure is more constant. These data imply that ''open'' chromatin configurations are more accessible and more repairable than compact, heterochromatic regions of the genome. As mentioned, (6-4)PDs are induced with sixfold greater frequency in linkers compared to nucleosomal core DNA. The nonrandom induction of the (6-4)PDs in more accessible regions of chromatin may, therefore, facilitate its rapid removal by the excision repair complex.

5.3.3 Developmental and Genetic Regulation of Excision Repair

The efficiency of DNA repair depends on the developmental state of a cell, tissue or organism. Both developmental and genetic attributes have made the nematode *C. elegans* a popular organism for probing many biological problems, including DNA repair. A striking phenotype of certain

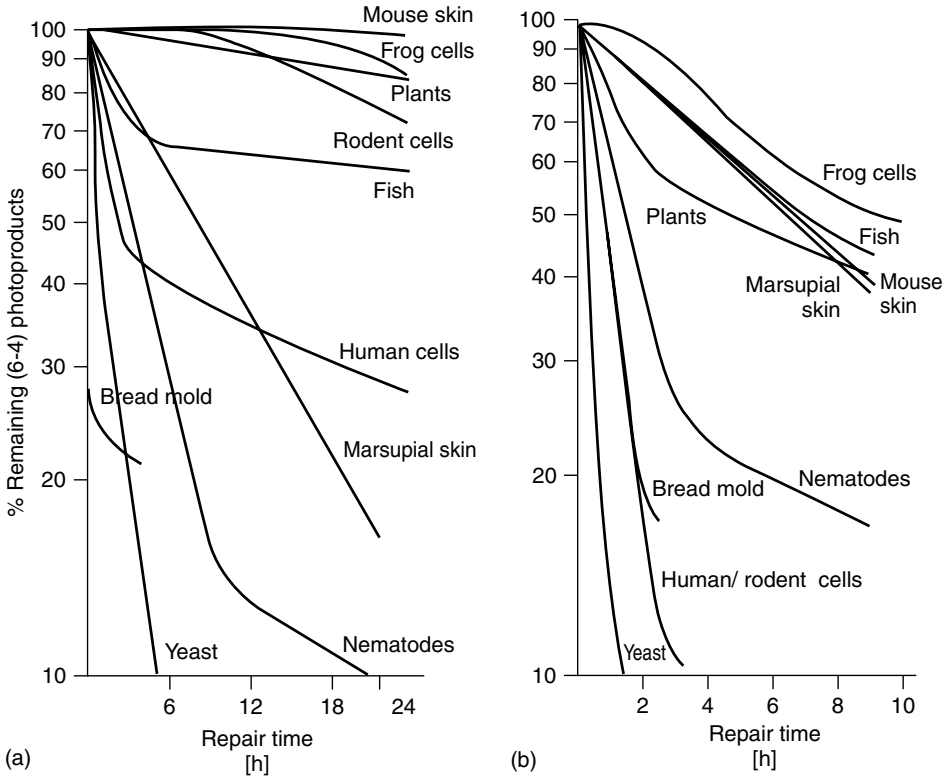

Fig. 10 Kinetics of CPD and (6-4)PD repair, radioimmunoassay of DNA repair of CPDs in various organisms. Organisms include *N. crassa* (bread mold), *S. cerevisiae* (yeast), *C. elegans* (nematode), *M. domestica* (marsupial), *Xiphophorus variatus* (fish), *A. thaliana* (plant), *X. laevis* (frog).

C. elegans mutants is the manifestation of stage-specific variation in UV hypersensitivity. For example, *rad-3* mutant nematodes are moderately hypersensitive when irradiated as embryos, but larvae are highly hypersensitive. Unlike wild-type nematodes, whose repair capacity remains relatively constant, the excision repair capacity of *rad-3* nematodes varies substantially throughout development. *Rad-3* embryos display a reduced capacity for excision repair, yet larvae assayed 24 h later are almost totally deficient in excision repair. The correlation between UV hypersensitivity and reduced excision repair capacity suggests that DNA repair in the nematode is developmentally regulated.

Evidence also suggests that DNA repair is developmentally regulated in higher eukaryotes. Excision repair of UV damage in cultured fish cells is very low, although significant excision repair is observed in primary embryonic cells. Similar regulation is seen in mice; exposure to photoreactivating light has no effect on CPD removal in adult mouse epidermal DNA or mouse fibroblasts in culture, yet significantly reduces the number of these lesions in the epidermis of neonatal mice; and excision (dark) repair of CPDs is much

more efficient in early embryos compared to adult mice.

DNA damage resulting from UVR is more efficiently repaired in proliferating basal cells in rodent and human epidermis than in terminally differentiated keratinocytes. A compelling generality one can derive from the developmental pattern of DNA repair in organisms and tissues is that more rapidly proliferating systems (i.e. stem cells, embryos, fetuses, larvae) have increased capacities for self-correction. Hence, those organisms most vulnerable to the lethal and mutagenic effects of genetic change are best able to tolerate it. DNA repair exhibits different developmental profiles in different organisms; thus, both ontogeny and phylogeny of DNA repair can vary substantially.

Selection of UV-sensitive rodent cells and the study of human sunlight-sensitive disorders have identified a large array of genetic loci that control the response of mammalian skin to UVR damage (Table 4). These loci are all characterized by significant increases in sensitivity to UVC or UVB radiation and include the excision repair cross-complementing (ERCC) series in rodent cells, XP, CS, TTD, and basal cell nevus syndrome (BCNS).

With the exception of BCNS, all of these disorders represent increased sensitivity to UVB and UVC wavelengths due to recessive mutations. BCNS exhibits a unique sensitivity to UVB radiation and is a dominant disorder. The recessive disorders can be considered as subsets within a large family of genes that regulate human cell DNA repair. These subsets are not mutually exclusive; CS complementation group C is identical to XP complementation group B; TTD overlaps with group D; XP group B corresponds to ERCC3 as well as to CS group B; XP group D corresponds to ERCC2.

XP is a rare autosomal recessive disease that occurs at a frequency of about 1 : 250 000 in the United States. Affected

Tab. 4 Complementation groups in XP and UV-sensitive Chinese hamster ovary (CHO) cells.

Group	*Human chromosome location*	*Central nervous system repair disorders*	*Relative DNA repair [%]*
Xeroderma pigmentosum			
A	9q34.1	Yes	2–5
B	2q21	Yes	3–7
C	3q25	No	5–20
D	19q13.2	Yes	25–50
E	11p11-12	No	50
F	16q13.1	No	18
G	13q32.3	Yes	<2
Variant	6p21	No	100
CHO (*ERCC*)			
1	19q13.2	–	Low
2 (XPD)	19q13.2	–	Intermediate
3 (XPB)	2q21	–	Intermediate
4 (XPF)	16q13.1	–	Low
5 (XPG)	13q 32.3	–	Intermediate

patients (homozygotes) have sun sensitivity resulting in progressive degenerative changes of sun-exposed portions of the skin and eyes, often leading to neoplasia. Some XP patients have, in addition, progressive neurological degeneration. Obligate heterozygotes (parents) are generally asymptomatic. The median age of onset is 1 to 2 years, with skin rapidly taking on the appearance of that seen in individuals with many years of sun exposure. Pigmentation is patchy, and the skin shows atrophy and telangiectasia with development of basal cell carcinomas (BCC) and squamous cell carcinomas (SCC). The frequency of cancers is about two thousand times that seen in the general population less than 20 years of age, with an approximate 30-year reduction in life span.

Cells from patients with XP excise CPDs and (6-4)PDs at reduced rates of 0 to 90% of normal, except for the variant group, which has a near-normal rate. The reductions are similar in all tissues thus far investigated, including skin *in vivo*, peripheral lymphocytes, fibroblasts, liver cell cultures, and tumor cells. There are seven complementation groups among patients who are deficient in excision repair, and an eighth, the XP variant, has a defect in replication of damaged DNA. Compared with normal cells, cells from XP groups A and D are very sensitive to the lethal effects of UV light and are unable to repair the CPD and the (6-4)PD. XP group A cells also have a reduced capacity to repair the Dewar pyrimidinone.

Group C is one of the largest groups and is often referred to as the ''classic'' form of XP. The patients show only skin disorders, which vary considerably in severity, depending on the climate. Tumors of the tongue have been observed in several patients. Cells have low but heterogeneous levels of excision repair (10–20% of normal) and are less sensitive to killing by UVR and chemical carcinogens than cells in groups A and D. This group is unique among the XP groups in that the repair defect is restricted to GGR with TCR functioning normally (Fig. 8). This raises the dilemma that high rates of cell killing, somatic mutation, and cancer from UV light in XP group C are associated with repair deficiencies in the nontranscribed regions of the genome. This in turn suggests that activating rather than silencing mutations may be important or that mutations may, in fact, arise from unrepaired lesions in the nontranscribed strand of active genes.

Group E is a rare group that exhibits mild symptoms and residual levels of repair that are between 50 and 100% of normal and lack a DNA-binding protein, p48, that is associated with a larger protein, p127. XPE patients carry mutations in the p48 gene. The role of this protein is unclear but it is dependent on p53 and involved in repair of nontranscribed regions of DNA. The absence of a homologous protein in rodent cells has been invoked to explain the reduced capacity of these cells in nontranscribed DNA.

XP variant cells have normal excision repair but lack a DNA low fidelity class-Y DNA polymerase, *hRAD30A* (Pol H) that is required for accurate bypass of CPDs during DNA replication. In its absence, XP variant cells are very susceptible to UV-induced mutagenesis and exhibit essentially the same symptoms as other XP patients. Carcinogenesis from UV damage in XP patients arises therefore from the loss of either NER capacity or Pol H; both lead to an increase in the amount of persistent DNA damage that becomes the substrate for error-generation (mutations, gene rearrangements, deletions etc.).

Cockayne syndrome is an autosomal recessive disease characterized by cachectic dwarfism, retinal abnormalities, microcephaly, deafness, neural defects, and retardation of growth and development after birth. Carcinomas of the skin as a result of hyper-photosensitivity are not seen in patients with CS, setting this disease apart from XP. CSB knockout mice however are sensitive to UVB carcinogenesis. Characteristic cellular changes in CS include a failure of DNA and RNA synthesis to recover to normal levels after UV-irradiation. The excision of DNA photoproducts from total genomic DNA of CS cells is normal, but repair of transcriptionally active genes is reduced. The CS gene products are involved in coupling excision repair to transcription, but their precise function is not yet clear. They may be involved in the ubiquitination and degradation of stalled RNA pol II at damaged sites.

Cockayne syndrome and XP group C therefore make an interesting contrast. CS cells repair only transcriptionally inactive genes, whereas XP group C cells repair only transcriptionally active genes. They show a similar increased sensitivity to cell killing, indicating that all regions of the genome must be repaired for normal survival. But only XP group C shows elevated mutagenesis and carcinogenesis, indicating that defective repair of transcriptionally inactive genes is more important for these endpoints. Mice with defects in XP or CS genes or both show elevated carcinogenesis, which raises questions of the different roles of NER in humans and mouse strains.

Trichothiodystrophy is a rare autosomal recessive disorder characterized by sulfur-deficient brittle hair and ichthyosis. Hair shafts split longitudinally into small fibers, and this brittleness is associated with levels of cysteine/cystine in hair proteins that are 15 to 50% of those in normal individuals. Patients also show physical and mental retardation of varying severity and often have an unusual facial appearance, with protruding ears and a receding chin. Mental abilities range from low normal to severe retardation. Several categories of the disease can be recognized on the basis of UV sensitivity and DNA repair. The most severe cases have repair deficiencies and complementation properties that place them in XP groups B and D. Most cases represent mutations in components of the transcription factor TFIIH and the symptoms of this disease indicate a role for this factor in development and hair growth.

6 Biological Consequences of DNA Repair

Air pollution has resulted in global decreases in stratospheric ozone concentrations and an increase in the amount of harmful solar radiation reaching the earth's surface. The effects of increased UVB radiation on the human population are complex: the obvious and direct consequences include increased skin cancer and accelerated aging; less obvious and more indirect effects include deterioration of world food crops and natural ecosystems. The role of UVR DNA damage as a mutagenic precursor of some types of skin cancer is well documented and such damage is undoubtedly involved in cell death and growth inhibition in environmental systems. Its importance in photoaging and immunosuppression is, however, less well understood, although data suggest that DNA damage may provide an important signaling event in these processes.

6.1 Photoaging

Photoaging of skin results from chronic exposure to sunlight and is distinct from chronological aging. Changes in the skin induced by chronic exposure to solar UVR can occur well before signs of chronic skin aging. Signs of photoaging occur exclusively on sites of the body that are exposed to sunlight such as the neck, face, forearms, and legs (in women) and are manifested as a leathery appearance, increased wrinkle formation, loss of elasticity, increased fragility, impaired wound healing, and the formation of lentigines (sunspots) and diffuse hyperpigmentation. Because of differential attenuation of UVR in the skin (i.e. longer wavelengths penetrate deeper), it is believed that the shorter solar wavelengths (UVB) are responsible for photoaging effects in the epidermis and longer wavelengths (UVA) for dermal effects. Hence, direct damage in DNA, such as CPDs and (6-4)PDs may play a role in epidermal photoaging and ROS generated by UVA may act through various signal transduction pathways that may or may not be mediated by DNA damage. Transcription factors such as AP-1 or NFκB are known to stimulate matrix metalloproteinases (MMPs) that degrade matrix proteins (e.g. collagen) within the dermis and result in loss of tissue integrity. A more likely connection between DNA damage and photoaging may involve mitochondrial DNA (mtDNA). Mitochondria are not able to repair CPDs or (6-4)PDs and recent evidence shows mutation frequencies in mtDNA at significantly greater frequencies than that observed in genomic DNA of sun-exposed skin cells. In addition to a putative role for UVB-induced damage, a central role of UVA-induced ROS has been postulated in generating the most common deletion mutations found in these cells. Such deletions have been associated with loss of mitochondrial function and the induction of the metalloproteinase MMP-1.

6.2 Immunosuppression

The immunosuppressive properties of solar UVR have been well studied and have important implications with regard to the epidemiology and control of infectious diseases as well as the progression of various types of cancer. It has been known for some time that UVR inhibits the immunological rejection of transplanted tumors. Two major areas of UVR-related immunosuppression have been under study, including the localized suppression of contact hypersensitivity, a delayed type hypersensitivity, and systemic immunosuppression, which is induced by high UVB, doses affecting immune responses at distant, nonexposed sites of the body. The molecular mechanisms underlying these phenomena are complex and some considerable attention has been directed toward identifying the targets of UVR immunosuppression and the role of DNA damage. Two chromophores have been identified in the epidermises, which participate in photoimmunosuppression, including urocanic acid and DNA. Urocanic acid accumulates in the stratum corneum and is converted from a trans- into a cis-form upon exposure to UVR. Removal of the stratum corneum has been shown to inhibit immunosuppression. Direct damage caused by UVB is considered to play a major role in UV-mediated immunosuppression. Accelerated removal of CPDs by exogenous application of a liposome cream containing DNA repair enzyme (i.e. T4 endonuclease V) resulted in complete abrogation of the immunosuppressive effects

of UVB. Enhanced repair by this topical treatment also suppressed cytokine release of interleukin-10 (IL-10) and tumor necrosis factor (TNF) by keratinocytes, both of which are implicated in the immune response. Suppression of DNA repair by the cytokine IL-12 may also play a role in immunosuppressed individuals.

6.3 Photocarcinogenesis

Carcinogenesis often appears to proceed by a multistep process, the first being an initiation event with subsequent promotional events that can often occur much later. One view of carcinogenesis correlates initiation with the induction of a small number of somatic mutations in a few critical genes, and promotion with further alterations in gene expression, copy number, and karyotype. Carcinogenesis appears to involve a process that destabilizes the genome with resulting variations in the activity of a large number of genes that change and develop over time. These include genes for cell-cycle regulation, checkpoint and damage response, detoxifying carcinogenic chemicals, DNA repair, and some 50 or more dominantly acting proto-oncogenes activated by mutation, deletion, translocation, or amplification, and tumor suppressor genes whose loss may contribute to the development of cancer. Two molecular mechanisms can be important in the initiation of carcinogenesis: activation of proto-oncogenes and inactivation of tumor suppressor genes and both are vulnerable to the lethal and mutagenic effects of UVR.

Skin cancers include at least three categories of tumor type: squamous cell carcinoma, basal cell carcinoma, and melanoma. These have distinct origins, molecular changes and etiology, and eventual outcomes, and each has characteristic genetic and solar components to their development. SCCs and BCCs appear to originate from different locations in the skin, and melanoma from the pigment cells. The initial damage produced by solar UVB to the skin is eliminated either by repair or by proliferation and exfoliation from the skin's surface. Some cells in the skin also die by apoptosis following exposure ("sunburn cells") resulting in the elimination of damaged cells. Stem cells for the epithelium are thought to reside in the bulge region of the hair follicles, but there are also secondary stem cells at the base of each column of epidermal transit amplifying cells in the epidermal proliferative units. Whether SCCs and BCCs come from different stem cells is currently unknown. A very low frequency of quiescent cells has been observed to retain DNA damage for long periods seemingly without repair or proliferation. The carcinogen-retaining cells may be stem cells, or damaged cells with the potential to become mutants once stimulated to proliferate.

The progression of molecular changes involved in SCC appears to be initiated by inactivating mutations in p53 that result in expanding clones in the sun-exposed areas of the skin that are initially confined within the proliferating units. These clones can be very frequent and can break out of the confines of the columnar structure of the proliferative units after chronic UVB irradiation. Over 90% of SCCs are reported to have p53 mutations that are characteristic of UV exposure, being in dipyrimidine sequences with notable frequencies of C–C to T–T changes. Several investigations have also identified activating mutations in the Ha-*ras* and N-*ras* oncogenes at codon 61, from solar UVR. However, although over 75% of UV-induced mutations are

generally C→T transitions at T–C or C–C CPD sites, the Ha-*ras* and N-*ras* activation occurred in tumors at a T–T site and are transversions not previously identified in model culture systems.

BCCs are exemplified by the hereditary disease, BCNS. The defect in BCNS appears to be in the human homolog of the *Drosophila* gene *PATCHED* (*PTC*), which is involved in embryonic patterning as well as in determining the fate of multiple structures in the developing embryo. Both somatic mutations in sporadic BCCs and single allele mutations in patients with BCNS, have provided strong evidence that this tumor suppressor is important in BCC tumorigenesis. The patched protein (PTC) is a transmembrane receptor, and with the coreceptor membrane protein Smoothened (SMO), regulates signal transduction by the extracellular protein Hedgehog (hH) that binds to PTC. Mutations in *SMO* have been identified in BCCs. Also, more than 50% of BCCs and 90% of SCCs contain mutations in p53 with a specific signature induced by ultraviolet light and many other gene amplifications and deletions have been detected.

Melanoma occurs in a hereditary form among approximately 5 to 12% of all patients. Although this is clinically and histologically indistinguishable from nonfamilial melanoma, there are differences in the age of diagnosis, lesion thickness, and frequency of multiple lesions. There are two known melanoma predisposition genes, CDKN2A and CDK4. CDKN2A functions as a cell-cycle regulatory protein that inhibits the activity of the cyclin D1 cyclin-dependent kinase 4 (CDK4) or 6 (CDK6) complex, which then act as negative regulators of growth by arresting cells at the G1 phase of the cell cycle.

6.4 Effects on the Environment

Global decreases in stratospheric ozone have been observed in recent years as a consequence of air pollution from natural or anthropogenic sources, such as volcanic eruptions and hydrocarbon (fuel) combustion. There is widespread concern about the effects of such atmospheric changes on the biosphere. Reduced ozone concentrations affect the intensity and spectral distribution of UVR at the earth's surface and up to at least 20 m deep in the oceans by increasing the amounts of biologically harmful wavelengths of UVB.

An increase in solar UV, as postulated from models of stratospheric ozone depletion, could significantly alter populations of marine and terrestrial plant and animal communities. Selection by UVR would result in reductions of UV-sensitive species and expansion of more UV-resistant species or clones. Trends of this sort would inevitably produce a more UV-resistant community; however, the consequences of changes in taxonomic structure on other parameters relevant to the ecosystem, such as primary production and trophic dynamics, are problematic. Decreases in total primary production have been documented during Antarctic ozone depletion and are expected at other latitudes.

The annual occurrence of springtime ozone depletion over the Antarctic provides a unique setting for monitoring the effects of increased UVB radiation on natural populations. Studies have been conducted on the induction and repair of UVB damage in various Antarctic bacterioplankton, phytoplankton, larval echinoderm, and fish species. The results indicate that great diversity in the photobiology of individual species exists with photoproduct

induction and repair varying considerably. Indeed, DNA-damage frequencies can vary a hundredfold and the ability of individual species to excise DNA photodamage ranges from negligible to near complete removal within 6 h. Parallel to this diverse molecular response, the ability of these organisms to survive the effects of UVB light is also extremely variable, correlating with DNA repair capacity. It is apparent that, within a cross-section of the Antarctic marine community, relatively sensitive and resistant phytoplankton species coexist.

Marine plankton are an important component of the oceanic food chain and are directly responsible for much of the world's oxygen production. Knowledge of the molecular and biological responses to UVB light at the species level will enable us to predict changes in the biomass and population diversity of marine ecosystems. Using plankton as a model, insight into the ultimate effects of stratospheric deozonation on other marine and terrestrial ecosystems can be extrapolated. Knowledge of the molecular biology of DNA damage and repair in selected plants and animals at different stages of their development will also allow us to identify species at risk and predict the consequences of deozonation on man and the earth's environment.

Keywords

DNA Library
A collection or bank of DNA clones generated from DNA of an organism that is either stored in bulk or in array in microplates. The relationship between the clones can be established by sequencing, by restriction mapping and/or by cross-hybridization.

Complementary DNA Library (cDNA Library)
A collection of clones of cDNA synthesized from RNAs present in a cell or an organism by reverse transcription *in vitro* using an enzyme named *reverse transcriptase*. In general, cDNA libraries are constructed from messenger (m) RNA.

Expression Library
A library of DNA clones that are created in an expression vector in order that the genes present in the library can be directly expressed in their host cells.

Genomic DNA Library
A collection of clones made from a set of DNA fragments representing the entire genome of an organism. The fragments can be generated either by partial digestion of source DNA with one or more restriction enzymes, or by physical shearing followed by fragment-end repair. Small-insert genomic DNA libraries are traditionally referred to as those cloned in the plasmid, phage, cosmid, or fosmid vectors, with an average insert size of up to 45 kbp. However, recent studies have shown that the plasmid, cosmid, and fosmid vectors are also capable of cloning and stably maintaining DNA fragments of greater than 300 kbp. The clones of small-insert genomic DNA libraries are often stored in bulk, and thus the libraries are unordered libraries. Large-insert genomic DNA libraries include those cloned in the bacteriophage P1 (P1),

bacteriophage P1-derived artificial chromosome (PAC), bacterial artificial chromosome (BAC), plant-transformation-competent binary BAC (BIBAC), plasmid-based clone (PBC) and yeast artificial chromosome (YAC) vectors, with an average insert size of 100 kb or greater. The clones of large-insert genomic DNA libraries are often arrayed in 96- or 384-well microplates, and thus the libraries are ordered libraries.

Bacteriophage λ
A phage that infects bacteria such as *Escherichia coli*. It has a complex set of regulatory mechanisms to determine whether it will lysogenize or lyze the host bacteria. The bacteriophage lysogenizes if it quietly inserts its DNA into the bacterial genome to become dormant and to be reproduced whenever the host bacterium reproduces. The bacteriophage lyzes the host cell if it hijacks the bacterium's cellular machinery to reproduce itself in order to infect more bacteria, causing the host bacterium to self-destruct shortly after infection. Bacteriophage λ is widely used as a cloning vector for genomic DNA and cDNA library construction.

Plasmid
A small circular genetic element that is stably inherited independent of the chromosome(s) of the host cell. Plasmids have been found in bacteria and fungi. They are widely used as cloning vectors to introduce foreign DNA into both bacterial and yeast cells and for genomic DNA and cDNA library construction.

Cosmid
Artificially constructed plasmid-based cloning vector containing the cos sequence of phage-λ. Therefore, cosmids can be packaged in the phage particles for infection into *E. coli*, permitting cloning of DNA fragments of up to 45 kbp in bacterial hosts.

Cloning Vector
A DNA molecule originating from a virus, a plasmid, or the cell of a higher organism into which a foreign DNA fragment of appropriate size can be integrated without loss of the vector's capacity for self-replication; vectors are used to introduce foreign DNA into host cells where it can be reproduced in a large quantity. Examples are plasmids, cosmids, BACs, PACs, BIBACs, PBCs, and YACs; vectors are often recombinant molecules containing DNA sequences from several sources. In general, a desirable DNA cloning vector should contain elements essential for DNA replication, multiple cloning sites, and selection for both transformants and recombinants (the clones containing inserts).

DNA libraries have been invaluable tools for molecular biology research. They have facilitated the study of the genes and genomes of complex organisms by providing a method of producing large amounts of easily manipulated DNA for the investigation of any region of interest from the cloned DNA representative of the entire genome. A DNA library is a collection of DNA clones constructed *in vitro* by inserting the fragments of source DNA into a cloning vehicle or vector, which contains all

elements required for the delivery of the foreign DNA fragments and stable propagation as a plasmid, a bacteriophage or an artificial chromosome in the host cells. Depending on their DNA source, DNA libraries can be categorized as cDNA libraries, genomic DNA libraries, and oligo libraries. The genomic DNA libraries could further be classified into plasmid, phage, cosmid, P1, BAC, PAC, BIBAC, PBC, and YAC libraries, according to the cloning vectors used. Genomic DNA libraries could be constructed with insert sizes from several up to a million base pairs (bp), depending on research purposes and cloning technologies. Many strategies and techniques have been developed and used for construction of DNA libraries from plants, animals, insects and microbes. DNA libraries are essential resources and tools for all research areas of molecular cell biology and molecular medicine, from gene discovery, cloning, and characterization to gene therapy.

1 History and Development

Recombinant DNA molecules, cloning vectors, and transformation of recombinant DNA into host cells are essential for construction of DNA libraries. The discovery and isolation of the restriction-modification system and DNA ligase had, for the first time, made it possible to reconstruct DNA into recombinant DNA molecules *in vitro*, and thus to construct DNA libraries. Although the restriction-modification system in *E. coli* was first reported in 1953 and DNA ligase was first isolated in 1967, it was not until the early 1970s that biological scientists started to develop recombinant DNA technologies using plasmid and bacteriophage λ as vectors. DNA fragments of interest were enzymatically digested and ligated into a replication-competent, receptive vector to form recombinant DNA clones. The population of individual recombinants was then reintroduced into appropriate host cells to form a DNA library.

In the past 30 years, the techniques and tools for DNA library construction have been developed and significantly advanced. As a result, the size of the DNA molecules that scientists are able to manipulate has been increased from 100 to 10 000 kbp, and the recombinant DNA molecules between cloning vectors and source DNA fragments for library construction can be constructed from dozens of base pairs to 2000 kbp in insert size. To facilitate construction of DNA libraries for different research purposes, a variety of DNA cloning vectors, including plasmid-based, phage-based and artificial chromosome-based, have been developed. Several methods have been developed to transform the recombinant DNA into host cells, including the chemical ($CaCl_2$) method with heat shock, the biological method via bacteriophage packaging and infection, and the physical method using electroporation. The efficiency of transformation has been increased from 10^5 to 10^{10} colony-formed units (cfu) or plaque-formed units (pfu) per microgram of vector DNA. Many different strains of host cells, including bacteria, yeast, and mammalian cells have been developed and used for DNA library construction.

1.1 Recombinant DNA Technologies

The quality of the DNA to be cloned is crucial for the construction of high-quality DNA libraries. Not only should the source DNA be pure, but the fragments of the DNA should also be large enough in size for library construction. This is especially true for the generation of clonable fragments using restriction enzymes (see below). In general, the sizes of the source DNA fragments should be at least 3- to 4-fold larger than the average insert size of the target DNA library. The widely used conventional DNA isolation methods only allow isolation of genomic DNA with a majority of fragments ranging from 50 to 150 kbp in size. The DNA isolated with these methods is suitable for the construction of DNA libraries with average insert sizes of 45 kbp or smaller; however, it is not suitable for the construction of DNA libraries with larger insert sizes such as bacterial artificial chromosome (BAC) and P1-derived artificial chromosome (PAC) libraries. Therefore, the techniques for preparation of high-molecular-weight (HMW) or megabase-size DNA were developed in the late 1980s. In the conventional DNA isolation methods, whole cells, protoplasts, or nuclei are isolated from tissues and lysed, from which naked DNA are purified. However, to isolate HMW DNA, the cells, protoplasts, or nuclei must be embedded in a low-melting-point (LMP) agarose matrix. Cell lysis, DNA purification, and subsequent manipulation must be carried out in the agarose matrix. Use of the agarose matrix has allowed the isolation of DNA with fragment sizes greater than 10 000 kbp. The isolation of DNA by using the megabase-size DNA isolation methods has enabled the construction of DNA libraries with average insert sizes of up to 1000 kbp. Although whole cells have widely been used to isolate HMW DNA from animals, yeast, and microbes, whole cells and protoplasts are not the optimal source for the isolation of HMW DNA from plants, because the plant metabolic substances in the cytoplasm often interact with the DNA, making the DNA no longer digestible with restriction enzymes. Therefore, the nuclei isolation method has been widely adopted for preparation of HMW DNA from plant species. It is this method that has allowed construction of large-insert DNA libraries from different plant species.

Agarose gels are a widely used matrix for DNA fragment separation according to size. In laboratories, DNA fragments are often fractionated on conventional agarose gels by electrophoresis. However, the conventional agarose gel electrophoresis does not allow separation of DNA fragments greater than 50 kbp. To facilitate manipulation of DNA fragments greater than 50 kbp, therefore, a pulsed-field gel electrophoresis (PFGE) system has been developed to resolve DNA fragments between several kilobase pairs and 10 000 kbp in size.

Generation of clonable fragments of an acceptable size range from the isolated DNA is an essential step for recombinant DNA construction and DNA library generation. DNA fragments for library construction can be generated by either physical shearing, or by partial digestion of DNA with a restriction enzyme (enzymatic method). The physical shearing method has proven useful for small-insert shotgun library construction for genome sequencing, whereas the enzymatic partial digestion method has widely been used for construction of large-insert DNA libraries, such as yeast artificial chromosome (YAC),

BAC, binary BAC (BIBAC), PAC and plasmid-based clone (PBC) libraries. The physical shearing method is independent of the distribution and frequency of particular restriction sites. Therefore, the fragments generated with this method are most randomly distributed in the genome, and the library constructed from such fragments is the most representative of the entire genome. However, the sheared DNA fragments have to be repaired by end-blunting, or modified by adding restriction site-containing synthetic linkers prior to cloning. In contrast, the enzymatic partial digestion method is dependent upon the distribution and frequency of particular restriction sites. Since the distribution of the restriction sites of a particular enzyme is not necessarily uniform throughout a genome, the library constructed from the partial digestion of DNA with a single restriction enzyme usually does not have an optimal representation of the source DNA. To overcome or minimize such problems for research, particularly involving whole-genome physical mapping and genome sequencing, two or more DNA libraries are constructed from the partial digestion of DNA with individual restriction enzymes that are complementary in the base compositions of their restriction sites. A major advantage of the enzymatic method is that the partially restricted fragments can be directly cloned, that is, no further enzymatic modification of the restricted fragment ends is necessary. For library construction, especially large-insert DNA library construction, at least four methods have been used to generate clonable DNA fragments: (1) varying the concentration of the restriction enzyme, (2) varying the time of digestion with the same amount of the restriction enzyme, (3) varying the concentration of a restriction enzyme cofactor (e.g. Mg^{2+}), and (4) varying the ratio of the restriction enzyme to the corresponding methylase.

Clonable DNA fragments generated with any of the currently used methods vary widely in size. Therefore, the clonable DNA fragments generated are often subjected to size selection. So far, at least two types of matrices, agarose gels, and sucrose gradients, have been used for DNA fragment size selection. However, agarose gels are the most popularly used matrix for this purpose. To select for DNA fragments smaller than 40 kbp, the conventional agarose gel electrophoresis is routinely used. Pulsed-field gel electrophoresis is the method of choice to select for DNA fragments larger than 40 kbp. The size-selected DNA fragments are then ligated into a DNA cloning vector for library construction.

1.2 Cloning Vectors of DNA Libraries

Since the advent of recombinant DNA technology in the early 1970s, hundreds of DNA cloning vectors have been constructed. Their versatility is represented not only by their cloning capacity as described above, but also by cloning sites, host range and functions, which appear to be limited only by the ingenuity and imagination of inventors. Whereas insertion of foreign DNA fragments into the first plasmid pSC101 was limited to a single restriction enzyme cleavage site and to *E. coli* as a host, most of the vectors currently in use carry multiple restriction-enzyme cleavage sites (polylinker sites) and have been modified for use with most common laboratory microorganisms. Many vectors now include dual origins of replication that enable them to be shuttled between host as dissimilar as *E. coli*, yeast, and even mammalian cells. Function-specific

vectors are now available that enable investigators to streamline particular research applications, such as to clone a genomic DNA fragment and a structural gene, to identify an open reading frame, to identify and isolate regulatory DNA sequences, for example, promoters, and terminators, to overexpress useful RNAs and proteins, and to determine the nucleotide sequence of genes, DNA segments, and the entire genome of an organism.

The DNA cloning vectors can be categorized into three groups – plasmid-based, phage-based, and artificial chromosome-based vectors. For instance, plasmid, cosmid, fosmid, BAC, PAC, and PBC are all plasmid-based vectors; bacteriophage λ, M13, and P1 are phage-based vectors; and YAC and mammalian artificial chromosome (MAC) are artificial chromosome-based vectors (Table 1).

A vector that is desirable for DNA library construction must have at least one element for DNA replication, a multiple cloning site and markers or mechanisms for selection of transformants and the clones containing recombinant DNA. Vectors that also provide additional functions, such as transformation via *Agrobacterium* in plants, have additional elements, such as T-DNA. Phage-based vectors, bacteriophage λ and P1, for example, use the capacity of packaging recombinant DNA into the phage heads for transformant and recombinant DNA clone selection, because the recombinant DNA molecules that are significantly larger or smaller than the natural genome size of the phage cannot be packaged into the phage heads. Most of the modern plasmid-based vectors use antibiotics for transformant selection and colony color (e.g. *LacZ* gene) or clone growth ability (e.g. *SacB* gene) for recombinant clone selection. Artificial chromosome-based vectors use auxotrophic complementation for transformant selection and colony color for recombinant clone selection. The biological method is usually used to transform the recombinant DNA constructed in the phage-based vectors, whereas the biological, chemical, and physical methods are used to transform the recombinant DNA constructed in the plasmid-based and artificial chromosome-based vectors (see below).

The cloning capacity of the vectors, that is, the insert size of foreign DNA that a vector is able to clone and stably propagate in the host cells, is not yet clear. The cloning capacity of the phage-based vectors is limited due to the limited capacity for packaging recombinant DNA into the phage heads; however, the cloning capacity of plasmid and artificial chromosome-based vectors seem to vary greatly. When the plasmid and cosmid vectors were initially developed, they were considered to be capable of cloning only up to 45 kbp. Recent studies have documented that they are capable of cloning and stably maintaining DNA fragments of over 300 kbp in *E. coli*. The increase in cloning capacity of the plasmids and cosmids was achieved with the recent development of technologies for HMW recombinant DNA construction and transformation. As new technologies for large DNA fragment cloning continue to develop, it can be predicted that the cloning capacity of the plasmid and cosmid vectors will be further increased, because *E. coli*, the widely used hosts of the vectors, is capable of stably maintaining and propagating at least 1500 kbp of foreign DNA.

Plasmids were first reported as molecular cloning vectors in 1973. This marked the beginning of a new era of molecular biology research and laid the groundwork for what was to become known

Tab. 1 Cloning vectors and systems of DNA libraries.

Vector type[a]	*Cloning capacity*[b] *[kbp]*	*Examples*[c]	*Structure*	*Year of appearance*[d]	*Host*	*Growth mode on agar plate*	*Number of copies/cell*

[d]The year indicates the year of appearance of the modern form of the vector, but not the first reported use of the vector type. "NA" indicates "Not Available."

as the biotechnology industry. Previously, the plasmid vectors were used only to construct DNA libraries with insert sizes ranging from several hundreds to several thousand base pairs. Although bacteriophage λ can package approximately 50 kbp of DNA into its heads, the phage itself requires at least 30 kbp of essential genes and elements for viability, which limits the cloning capacity of phage λ vector to no more than 20 kbp.

Until the early 1990s, cosmids were the widely used vectors for cloning large-insert DNA fragments in *E. coli*. They allowed cloning of DNA fragments up to 45 kbp. Cosmid vectors had not only the advantage of the high efficiency of cos-mediated bacteriophage λ packaging for transformation but also had the advantage of small plasmid vectors. To facilitate reproduction of the recombinant DNA in the host cells, most, if not all of the cosmids previously developed are maintained as multiple copies per cell. However, while the DNA libraries cloned in the cosmid vectors were extensively used in genome research, the rearrangements of the cloned DNA were observed in some host *E. coli* strains and attributed to the multiple copies of the cosmids within a host cell. Therefore, fosmid vectors were designed from the single-copy F plasmid of *E. coli*. As with cosmids, fosmids also contain cos sites for cos-mediated phage λ packaging; therefore, they have the same cloning capacity as cosmids. Even though fosmids appeared to be more stable than the cosmid clones, instability of fosmid clones was also observed in some *E. coli* host strains. Therefore, further studies were needed to determine the relationships of clone stability with the copy number of vectors and host strains.

Cosmid cloning vectors had played an important role in large-insert DNA library construction in the early stages of genome research. However, the insert sizes (up to 45 kbp) of the cosmid DNA libraries were insufficient for genome research of species with large genomes. Therefore, the artificial chromosome-based YAC cloning system was developed in 1987. Using yeast as the host, YAC vectors permitted the cloning of fragments greater than 1000 kb, which represented a revolutionary advance in cloning capacity. However, several problems, such as high level of chimeric clones, insert rearrangement and difficulty in purifying cloned insert DNA, were observed in this system. These problems limited the utility of YAC libraries for genome research.

The development of alternative systems that would be capable of cloning and maintaining large DNA fragments in bacteria, therefore, became imperative. In the early 1990s, the P1, BAC, and PAC systems were developed. The P1 vectors were derived from the bacteriophage P1 with a genome size of about 100 kbp. Since the P1 recombinant DNA is transformed into the host *E. coli* cells by the same procedure as in bacteriophage λ, namely, packaging and infection, the P1 vectors have a cloning capacity of up to 100 kbp. The BAC vectors were based on the single-copy F factor and derived from the fosmid vectors. Because BAC constructs are transformed into the host *E. coli* cells by electroporation, instead of $CaCl_2$/heat shock, BACs having insert sizes of over 300 kbp could be obtained. The modification of the P1 vector combined with the BAC electroporation technology led to the development of the PAC system. Therefore, the PAC vectors have a cloning capacity similar to the BAC vectors. In comparison with the YAC system, despite their smaller insert sizes, BACs and PACs are much more stable in the host cells, much lower in chimerism,

and more easily purified from the host chromosome DNA, and therefore, have been rapidly adopted for genome research.

Unlike small-insert clones, the entire insert of the large-insert BACs and PACs are difficult to subclone. Therefore, it is desirable to develop a cloning system that is not only capable of cloning and stably propagating foreign DNA fragments as large as BACs and PACs, but can also directly be transformed into plants. Therefore, an *Agrobacterium*-mediated, plant-transformation-competent BIBAC system was developed in 1996. In addition to the features of the BAC vectors, the BIBAC vector has a T-DNA cassette to facilitate BAC insert transfer into plants via *Agrobacterium*. As expected, the BIBAC vector is capable of stably cloning and propagating DNA fragments as large as BACs and PACs, and also capable of transferring the BAC inserts into plants. This has significantly streamlined the use of the large-insert clones for positional cloning, functional analysis of genomic sequences, and genetic engineering.

BAC, PAC, and BIBAC are all based on a single-copy "artificial chromosome." Nevertheless, the conventional plasmids or cosmids that were previously designed for different research purposes were later found to have the same capacity as the BAC, BIBAC, and PAC vectors for large fragment cloning and stable maintenance in *E. coli* strain DH10B, the host strain of almost all BAC and PAC libraries constructed to date. The breakthrough in the cloning capacity of the conventional plasmid and cosmid vectors clearly resulted from the use of the HMW recombinant DNA technique and the electroporation technology for transformation as in BACs and PACs. Since the plasmids and cosmids are not single-copy as the BAC and PAC vectors, the high stability of the large-insert PBCs in the host cells indicated that the stability of bacteria-based large-insert clones is not contingent on the unique copy number of the clones in a host cell. These findings have not only established concepts of large DNA fragment cloning in bacteria but have also indicated that many of the plasmid-based vectors previously developed for different biological research purposes could be used as vectors for large-insert DNA library construction in *E. coli*.

1.3 Transformation

DNA library construction also involves techniques of transformation by which the recombinant DNA constructed *in vitro* is delivered into the host cells where it is propagated. As recombinant DNA technologies and DNA cloning vectors evolved, techniques for several transformation methods have been developed and used for DNA library construction. There are three transformation methods – chemical ($CaCl_2$/heat shock), biological (*in vitro* packaging and infection), and physical (electroporation). As described above, although the biological method is routinely used to transform the phage-based vectors such as bacteriophages λ and P1, all three methods are used to transform the plasmid- and artificial chromosome-based vectors such as plasmids, cosmids, fosmids, BACs, PACs, PBCs, YACs, and MACs. The chemical and biological transformation methods were developed when the recombinant DNA research was initiated in the 1970s. At present, they are still widely used for DNA cloning and library construction. During the past 30 years, many procedures have been developed, and the transformation efficiency has been

increased several-fold. Now it is routine to obtain a transformation efficiency of 10^9 cfu μg^{-1} plasmid vector DNA using these transformation methods. The electroporation transformation method was developed a decade ago. It was this method that made it possible to construct large-insert DNA libraries in bacteria. The electroporation transformation method is much simpler than the previously developed chemical and biological methods and has a much higher transformation efficiency, greater than 10^{10} cfu μg^{-1} plasmid vector DNA. Therefore, it has been rapidly adopted for construction of different DNA libraries, including cDNA libraries, large-insert BAC, PAC, BIBAC, and PBC libraries and small-insert plasmid libraries.

1.4 Host Systems

Host cells that are competent for DNA library construction must be capable of stably maintaining and propagating cloned foreign DNA, and have high transformation efficiencies. As the recombinant DNA technologies developed, several host systems that are suitable for DNA cloning and library construction have been developed. According to the sources of the hosts, they can be categorized into bacterial, *Saccharomyces cerevisiae* (yeast), mammalian, and other organism hosts (Table 2). Bacterial *E. coli* is the most widely used host system for DNA library construction. Wild-type *E. coli* strains are highly proficient in recombination, which causes deletions and rearrangements through intramolecular recombination and intermolecular recombination as well, in the case of multicopy vectors at the high repetitive sequences cloned. Poor clonability also results from incompatibility of the foreign DNA with the natural host restriction and modification systems. To reduce the ability of the bacterial host to modify cloned DNA fragments in such ways, many *E. coli* mutations have been identified or created in

"NA" indicates "Not Available."

host systems available for DNA library construction. For example, the host *E. coli* strains DH5α and DH10B and their derivatives are widely used for the construction of plasmid, bacteriophage and cosmid libraries, and DH10B is routinely used for the construction of BAC, PAC, BIBAC and PBC libraries.

The budding yeast *S. cerevisiae* is a host system that is widely used for DNA cloning and library construction in yeast. Yeast is a single-cell eukaryotic organism and thus has all the basic features and mechanisms of eukaryotes. Not only is yeast as well studied as *E. coli*, and amenable to large-scale isolation techniques, but it is able to carry out some eukaryote-specific processes, such as posttranslational processing of eukaryotic proteins, eukaryotic DNA replication, telomeric function or functional chromosomes. These features and mechanisms have rendered the yeast host system more advantageous than the bacterial host system for functional analysis of eukaryotic genes. A number of different *S. cerevisiae* host strains are available to meet various library applications for studying insertion, deletion, alteration, and expression of genes. For YAC library construction, the primary requirement of a host is its ability to be transformed at reasonably high frequencies with large-insert DNA. AB1380 and a few other strains have been found suitable for this purpose.

In addition, mammalian cells have been used as a host system for MAC library construction. *Bacillus subtilis* has the ability to secrete proteins into growth medium and has been used as a host system for industrial production of recombinant proteins. Baculoviruses that infect insect cells have gained attention as a host system for production of glycosylated protein at very high levels.

2 Types of DNA Libraries

In the past 30 years, many DNA libraries have been developed for different molecular biology research purposes. The libraries can be categorized into cDNA, genomic DNA, and oligo libraries by their source DNA; plasmid, phage, cosmid, fosmid, P1, BAC, PAC, BIBAC, PBC, YAC, and MAC libraries by their cloning vectors; or general, binary, and expression libraries by their functions. Both cDNA and genomic DNA libraries could be general, binary, or expression libraries, whereas cDNA libraries could be plasmid, phage, or cosmid libraries and genomic DNA libraries could be plasmid, phage, cosmid, fosmid, P1, BAC, PAC, BIBAC, PBC, YAC, or MAC libraries.

2.1 cDNA Libraries

cDNA libraries are those DNA libraries constructed from DNA that are reverse-transcripted from and complementary to an organism's RNA pools. cDNA can be prepared from any source RNA, including coding and noncoding RNA, isolated from single-cell organisms, cultured cells and isolated tissues. However, almost all cDNA libraries are generated from total mRNAs in a cell representing all protein-encoding genes that are being expressed in the cell at a particular time, developmental stage, or treatment. The polyadenylated mRNA had previously undergone posttranscriptional editing and removal of any intervening sequences (introns). Thus, the copy of a gene in an mRNA or cDNA usually contains an uninterrupted sequence encoding the gene product.

A high-quality cDNA library should not only contain the sequences of all

genes expressed at the time when the RNA samples are collected but should also be full length and balanced in the copy number of every gene expressed. The probability that a given mRNA is represented in a cDNA library can be calculated by the following formula:

$$p(x) = [1-(1-f)_n]$$

where n is the number of recombinant clones and f is the frequency of a particular mRNA. Since a typical somatic cell contains approximately 0.6 pg of mRNA, approximately 500 000 mRNA molecules are present in a cell (0.6 pg/11 $\times$ 10^{-7} pg/1 mRNA molecule) if the average size of an mRNA is 2000 bases (11 $\times$ 10^{-7} pg). Accordingly, the probability of obtaining a rare mRNA (one copy per cell, $f = 1/500\,000$) in a library of 5 000 000 and 1 000 000 recombinant clones, would be 99.9 and 86.5% respectively.

In order to construct a high-quality cDNA library, it is essential to isolate full-length mRNAs encoding full-length protein sequences in the subject cells or tissues. Libraries made from fragmented mRNA would not preserve the full open reading frames of the genes, thus rendering the resultant partial-length cDNA libraries less useful. Message RNA tends to be a transient species by design as cells have developed complex posttranscriptional mechanisms to regulate gene expression through mRNA decay. The mRNA decay problem can be overcome through specialized procedures that seek to inactivate ribonuclease, an enzyme that cleaves RNAs, concomitantly with mRNA extraction from intact tissues.

Another concern of a high-quality cDNA library is the copy number balance of each gene expressed in the library. Such copy number-balanced cDNA libraries are often obtained through a process named normalization of cDNA populations. The mRNAs of a typical somatic cell are distributed into three frequency classes: prevalent, intermediate, and rare (complex). The classes at the two extremes, representing 10% and 40 to 45% of the mRNA species respectively, include the members occurring at vastly different relative frequencies. In general, the most prevalent class consists of approximately 10 mRNA species, each represented by 5000 copies per cell, whereas the class of high complexity comprises 15 000 different species, each represented by only 1 to 15 copies. Therefore, for a variety of research purposes, a normalization procedure is needed to bring the frequency of each clone in a cDNA library within a narrow range.

Plasmids, phages, or cosmids have widely been used as cloning vectors for cDNA library construction. Many procedures have been developed for cDNA library construction, such as directionally cloned cDNA libraries followed by normalization. cDNA libraries have served as, and will continue to be, one of the most important resources for gene mapping, discovery, cloning, expression, and functions (see below). cDNA libraries can be screened either by detection of cDNA inserts using polymerase chain reaction (PCR)- or hybridization-based methods, or by detection of RNA or protein expression products encoded by the cDNA inserts. PCR- or hybridization-based library screening methods are the same in principle for screening cDNA libraries and genomic libraries. For PCR-based library screening, super pools, plate pools, column pools, and row pools must be generated from the library and used as templates of PCR. The PCR primers are designed and synthesized according to the sequences of the existing genes. For the

hybridization-based library screening, the library should be blotted onto nylon membranes or filters. Either synthetic oligos (e.g. overlapping oligos named *Overgos*) designed according to the gene sequences or the partial or entire sequences of the genes could be used as probes. The probes are labeled with one or more radioactive or fluorescent nucleotides and hybridized to the library that is blotted onto the nylon membranes. Colonies or plaques that contain the inserts complementary to the probe can then be detected and isolated. The cDNA expression libraries can be screened on the basis of affinity of the target gene product to antibodies, proteins, or small-molecule ligands. In addition, functional properties can be screened for, such as catalysis or induction of transcription of a reporter gene.

2.2 Genomic DNA Libraries

In contrast to cDNA libraries, genomic DNA libraries are constructed from DNA sequences derived from an organism's chromosome(s) or entire genome. Early genomic DNA libraries were constructed in the plasmid, bacteriophage, and cosmid vectors, and had average insert sizes of up to 45 kbp. These libraries are suited for isolation and characterization of most genes, but not for the genes or gene clusters that span a large physical distance in the species with large genomes. Cloning and characterization of such genes or gene clusters require libraries that accommodate larger inserts. Furthermore, recent genome research and analysis require DNA libraries with even larger inserts. Therefore, YAC libraries that have average insert sizes of over 1000 kbp were developed for several plant and animal species. Nevertheless, the YAC libraries have high levels of chimerism, are unstable in inserts, and difficult to purify cloned insert DNA, all of which have limited their utility in genome research. The advent of bacteria-based large-insert cloning systems, BAC, PAC, BIBAC, and PBC, has shed light on large-insert genomic DNA library construction and its applications in genome research. Although the insert sizes of the BAC, PAC, BIBAC, and PBC libraries do not approach those of YAC libraries, they are stable in the bacterial hosts and have few chimeric clones. Most importantly, high-quality and high-quantity insert DNA of the large-insert bacterial clones can readily be purified by using the simple plasmid-based DNA preparation procedures (Fig. 1).

Three methods, PCR-based DNA amplification, physical shearing, and enzymatic digestion, have been used to prepare clonable DNA fragments for construction of genomic DNA libraries. PCR products are used to construct genomic DNA libraries specific to the sequences containing the primer binding sites, for which specific plasmid-based vectors have been developed. As described above, the physical shearing method generates a series of partially overlapping fragments distributed evenly along a genome. Thus, it has widely been used to produce DNA shotgun libraries for genome sequencing. This method has contributed to the genome sequencing of *Arabidopsis*, human, *Drosophila*, mouse, and rice, and will continue to be one of the most important tools for genome sequencing.

Restriction enzymes, either frequent (4 bp) or rare (6 or 8 bp) cutters, have also been used to produce DNA fragments for construction of genomic DNA libraries of

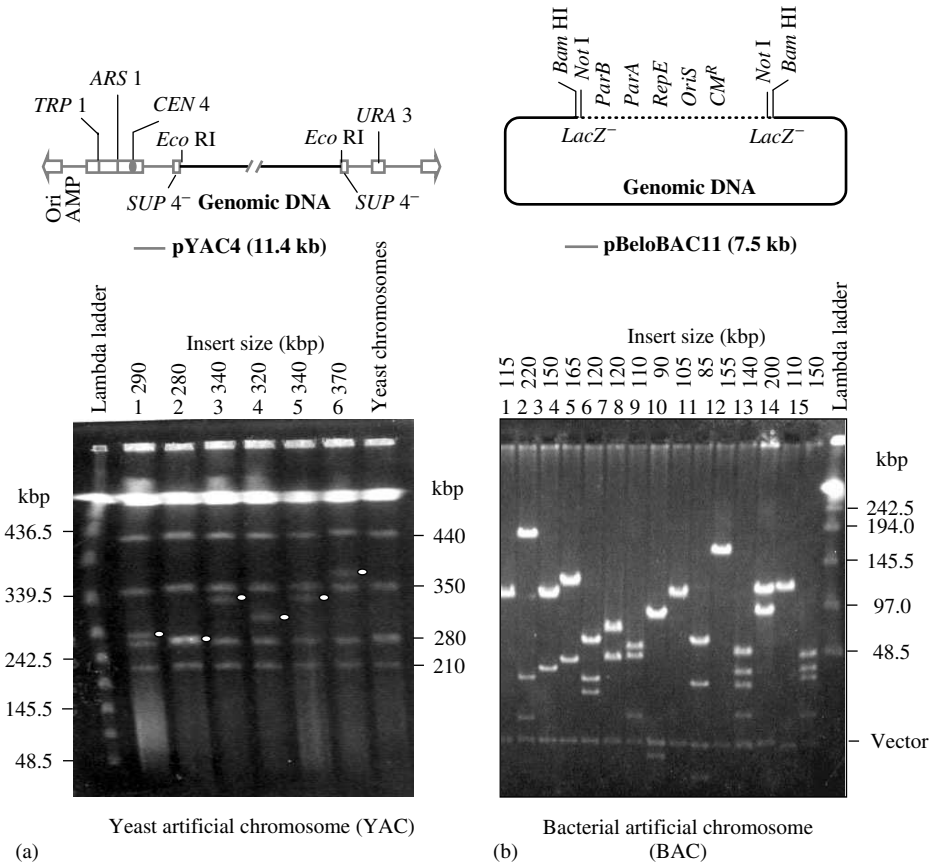

Fig. 1 (a) A yeast artificial chromosome (YAC) constructed in the YAC vector pYAC4 (top) and YACs fractionated on a pulsed-field gel (bottom). In the YAC construct, the terminal arrows indicate the telomeres, *CEN4* is the centromere of the artificial chromosome; and the bold-faced *Eco* RI is the cloning site. For YAC analysis, YAC DNA was isolated, subjected to PFGE, stained, and photographed. The YACs on the gel are indicated by bullets, and the bands appearing in all lanes are the yeast chromosomes. The YAC clones have a size range from 280 to 370 kbp; (b) A bacterial artificial chromosome (BAC) constructed in the BAC vector pBeloBAC11 (top) and BACs fractionated on a pulsed-field gel (bottom). In the BAC construct, the bold-faced *Bam* HI is the cloning site. For BAC analysis, BAC DNA was isolated, digested with *Not* I to release the inserts, subjected to PFGE, stained, and photographed. The band appearing in all lanes was derived from the BAC vector and the remaining bands were from the insert DNA. The BAC clones have an insert size range from 85 to 220 kbp.

different insert sizes. Although the complete digestion of genomic DNA with a restriction enzyme can be used for genomic DNA library construction, the clones of the resulting library do not overlap, which is undesirable for many aspects of molecular biology research. Therefore, most genomic DNA libraries were constructed from the partial digestions of source genomic DNA. The partial digestion method has been widely used in the construction of large-insert genomic DNA libraries. Because

large DNA fragments become dramatically more sensitive to physical shearing as their sizes increase, making it impossible to maintain the integrity of chromosome size in DNA molecules, specialized protocols have been developed that enable the cloning of DNA fragments of several hundred kilobase pairs, such as BAC, PAC, BIBAC, PBC, and YAC libraries.

The development of large-insert DNA libraries has not only facilitated cloning and characterization of genes and gene clusters that span large genomic regions but, importantly, it has also reduced the number of clones needed for a complete genomic DNA library, and thereby allowed each clone to be arrayed in multiple-well (384 or 96) microplates. In contrast, small-insert genomic DNA libraries are often maintained in bulk because of the prohibitively large number of clones needed for a complete library. The ability to array each individual clone of a large-insert DNA library in microplates has significantly facilitated isolation of clone(s) of interest from the library. Moreover, each arrayed clone has a permanent address that can be easily shared among investigators who have access to the library, along with any available information such as genes and nucleotide sequences contained in the clone. As such, data about a specific clone can rapidly accumulate, and the clone becomes more valuable through the contribution of the whole research community. At the present time, arrayed, large-insert genomic DNA libraries in forms of arrayed plates, high-density clone filters and/or DNA pools from a variety of plants, animals, human, and microbes are publicly available at several genomic resource facilities, such as http://hbz.tamu.edu, http://informa.bio.caltech.edu/lib_status.html, http://www.resgen.com/, http://www.chori.org/bacpac, and http://www.genome.clemson.edu/groups/bac/libraries_genomic.html.

Large-insert genomic DNA libraries have been widely used for a variety of molecular biology research studies ranging from gene discovery, cloning, and genome physical mapping to genome sequencing (see below). Studies showed that the representation of a genomic DNA library for the entire genome is of significance for use of the library in molecular biology research. Theoretically, the probability (p) that a given genomic sequence is present in a library can be estimated by a formula as follows:

$$p = 1 - e^{-n}$$

where n is the number of genome equivalents of the library, which equals the product of the number of total clones and the average insert size divided by the genome size. Table 3 shows the number of clones that are needed to have a 99.9% probability of obtaining a particular DNA sequence from a genomic DNA library with an average insert size of 50, 100, 150 or 500 kbp for *Arabidopsis, Drosophila*, rice, human, and wheat respectively. For a genome of a given size, the larger the clone inserts, the fewer the clones that are needed for a genomic DNA library. Large inserts are also significant for the efficiency and success of genome research, such as chromosome walking, and regional or whole-genome physical mapping and sequencing. The larger the inserts the fewer the steps, and the higher the likelihood of successfully walking a genomic region. The probability of success of completing a chromosome walk increases linearly as average insert sizer of the library increases from 50 to 150 kbp; however, there is little increase in probability of chromosome walking success once the average insert size exceeds 150 kbp.

Moreover, studies further showed that the theoretical (calculated) probability of genome coverage of a large-insert genomic DNA library constructed with a single restriction enzyme is about 15% lower than the genome coverage estimated by library screening. This implies that when the library is screened with random DNA markers, only about 85% of the markers are represented by one or more positive clones, whereas the remaining 15% are not represented in the library. The studies also showed that the genome coverage of the library could not be increased significantly by simply increasing the number of clones in the library. This is due to at least two notable reasons. First, some genomic regions may be lethal or poorly clonable, maintained and/or propagated in the host system; to clone these DNA sequences, a different vector and host system is needed. Second, the restriction sites of the enzyme used for the library construction are not uniformly distributed along the genome; consequently, the genomic regions having too many or too few restriction sites of the enzyme are difficult to clone because the small (<50 kbp) and large (>400 kbp) DNA fragments generated by partial digestion are removed during the size selection of large-insert DNA library construction. Therefore, it is recommended that at least two restriction enzymes with different nucleotide contents (AT-rich and GC-rich) in their restriction sites be used for large-insert genomic DNA library construction. This approach would minimize the bias of clone distribution along the genome, and thus achieve libraries of truly high genome coverage, because the large-insert DNA libraries constructed with this approach are shown to be complementary to each other, similar to mechanically sheared shotgun libraries.

In addition, unlike small-insert clones, the entire inserts of large-insert clones are difficult to subclone for functional analysis of the inserts by genetic transformation. This is because it is difficult to find an enzyme whose restriction sites flank the cloning site of the vector, but are absent in the large insert of the clone. Although the restriction enzyme *Not* I, a rare 8-bp cutter, is used to subclone the inserts of large-insert clones into transformation-competent binary vectors, it is present at an average frequency of one restriction site in every 65 536 bp in a genome, which is smaller than the 150-kb average insert size of a large-insert DNA library. Studies showed that the frequency of the *Not* I sites is much higher in the genomes of monocotyledonous plant species than those of dicotyledonous plant species. Therefore, it is desirable to construct large-insert DNA libraries in binary vectors that are capable of stably cloning and maintaining large DNA inserts, and that are also competent for large DNA fragment transformation. If the large-insert binary libraries are used for whole-genome physical mapping and sequencing, the ability of the binary clones to directly transform plants would significantly streamline the functional analysis of genomic sequences by genetic transformation.

Great efforts are needed to construct a large-insert DNA library for a species with a huge genome, for instance, common wheat (16 000 Mbp/1C) (see Table 3). According to the above formula, the higher the genome coverage the higher the probability of obtaining a clone of interest from the library. However, the increase in library genome coverage would increase the cost and effort that go into library production, storage, and manipulation. Therefore, an efficient genome coverage

Tab. 3 The number of clones needed for a 99.9% coverage genomic DNA library with an average insert size of 50, 100, 150, and 500 kbp respectively, for several species.

Species	*Genome size*	*Average insert size [kbp]*			
	[Mb/1C]	*50*	*100*	*150*	*500*
Arabidopsis	145	2.0×10^4	1.0×10^4	6.7×10^3	2.0×10^3
Drosophila	180	2.5×10^4	1.3×10^4	8.3×10^3	2.5×10^3
Rice	430	5.9×10^4	3.0×10^4	2.0×10^4	5.9×10^3
Human	3000	4.1×10^5	2.1×10^5	1.4×10^5	4.1×10^4
Wheat	16 000	2.2×10^6	1.1×10^6	7.4×10^5	2.2×10^5

of a large-insert DNA library would be helpful for use of the library in genome research. Although a DNA library with 4.7 x genome equivalents is equivalent to a 99% library according to the above formula, it is recommended that the total number of clones with an average insert size of at least 150 kb derived from two or more restriction enzymes and equivalent to a maximum of 10 x haploid genomes is sufficient for most genome research purposes, including global genome physical mapping and genome sequencing. This is supported by the whole-genome shotgun sequencing of *Haemophilus influenzae*, *Mycoplasma genitalium*, *Anopheles gambiae*, and the euchromatic genome portion of the *D. melanogaster*, and by whole-genome physical mapping of *Arabidopsis*, rice, and soybean, in which the numbers of clones equivalent to 6 – 10 x haploid genomes were used.

3 Construction of DNA Libraries

Construction of cDNA and genomic DNA libraries are essentially the same in principle; both include preparation of clonable DNA fragments, preparation of vectors, ligation of the clonable DNA fragments into the vectors, transformation of the ligation mixture into host cells, and library storage. The major difference between cDNA and genomic DNA library constructions is the preparation of clonable DNA fragments. For cDNA library construction, the clonable cDNAs are prepared from mRNA, whereas for genomic DNA library construction, the clonable DNA fragments are prepared from genomic DNA. The method that is used to transform the DNA/vector ligation into host cells depends on the vectors used for the library construction. For the construction of plasmid, M13, cosmid, fosmid, BAC, PAC, BIBAC, and PBC libraries, the electroporation method is widely used to transform the ligations into *E. coli* host cells, although the cosmids and fosmids were initially designed to transform into *E. coli* cells through the phage *in vitro* packaging and infection method. For the construction of bacteriophage λ and P1 libraries, the phage *in vitro* packaging and infection method is used to transform the ligation into *E. coli* host cells. For YAC library construction, the ligation is transformed into yeast host cells using the chemical method through yeast spheroplasts. Small-insert DNA libraries are usually maintained in bulk, while large-insert DNA libraries are arrayed in 96- or 384-well microplates. Nevertheless, small-insert DNA libraries

for special research purposes, such as expressed sequence tag (EST) sequencing and genome sequencing, are also arrayed in 96- or 384-well microplates. Outlined below is the construction of cDNA and genomic DNA libraries to demonstrate the principles and methods of DNA library construction.

3.1 cDNA Libraries

cDNA libraries are crucial tools for the study of tissue-specific genes and their expression. A customized cDNA library should contain a stable representation of the mRNA present in a specific tissue at the time of tissue collection. Four steps are often involved in the construction of a typical cDNA library (Fig. 2).

3.1.1 Preparation of Double Strand cDNA

1. *From mRNA to double strand cDNA*: ''Reverse transcription'' is a process whereby genetic information contained in an mRNA is converted back into a double-stranded DNA form. This DNA is named complementary DNA, or cDNA. The enzyme responsible for this process is an RNA-dependent DNA polymerase called reverse transcriptase. Reverse transcriptases have traditionally been isolated from viruses whose genomes are actually in an RNA form and must be converted to duplex DNA during propagation. These viruses typically carry a functional reverse transcriptase along with their mRNA genetic component when they infect cells. One of the most common commercially available reverse transcriptases is purified from moloney murine leukemia virus (MMLV). MMLV uses mRNA as a template, but requires a primer because it can extend a DNA primer, but cannot synthesize one.
2. One of the useful features of eukaryotic mRNA is the presence of the 3′ poly A tracks. They provide a unique method to synthesize cDNA complementary to the original mRNA strand from a variety of different eukaryotic mRNAs using poly dT as a single primer. When the first strand of cDNA is synthesized, the mRNA/cDNA hybrid duplex is developed (see Fig. 2).
3. Nicks in the RNA half of the hybrid molecule can be introduced via the action of the enzyme RNase H. This enzyme exhibits endonucleolytic cleavage of the RNA moiety of the RNA/DNA hybrids, as well as 5′ → 3′ and 3′ → 5′ exoribonuclease activity. In other words, it will nick the RNA and then proceed to digest it back in both directions.
4. These RNA fragments can now serve as primers for the second strand cDNA synthesis by *E. coli* Polymerase I (Pol I). This enzyme also translates the ''nicks'' to remove the RNA primers.
5. T4 DNA ligase ligates the nicked DNA and develops the whole second strand cDNA. Therefore, the double strand (ds) cDNA is completed. The ds DNA has either a residual 5′ RNA cap region, or a gap at the 5′ end of the original mRNA strand.

3.1.2 Insertion of cDNA into a Plasmid Vector

In order to complete the construction of a cDNA library, the cDNA needs to be maintained and propagated. This can be accomplished by inserting the cDNA into an appropriate plasmid, cosmid, or phage. Here we use a plasmid vector as an example because plasmid vectors used

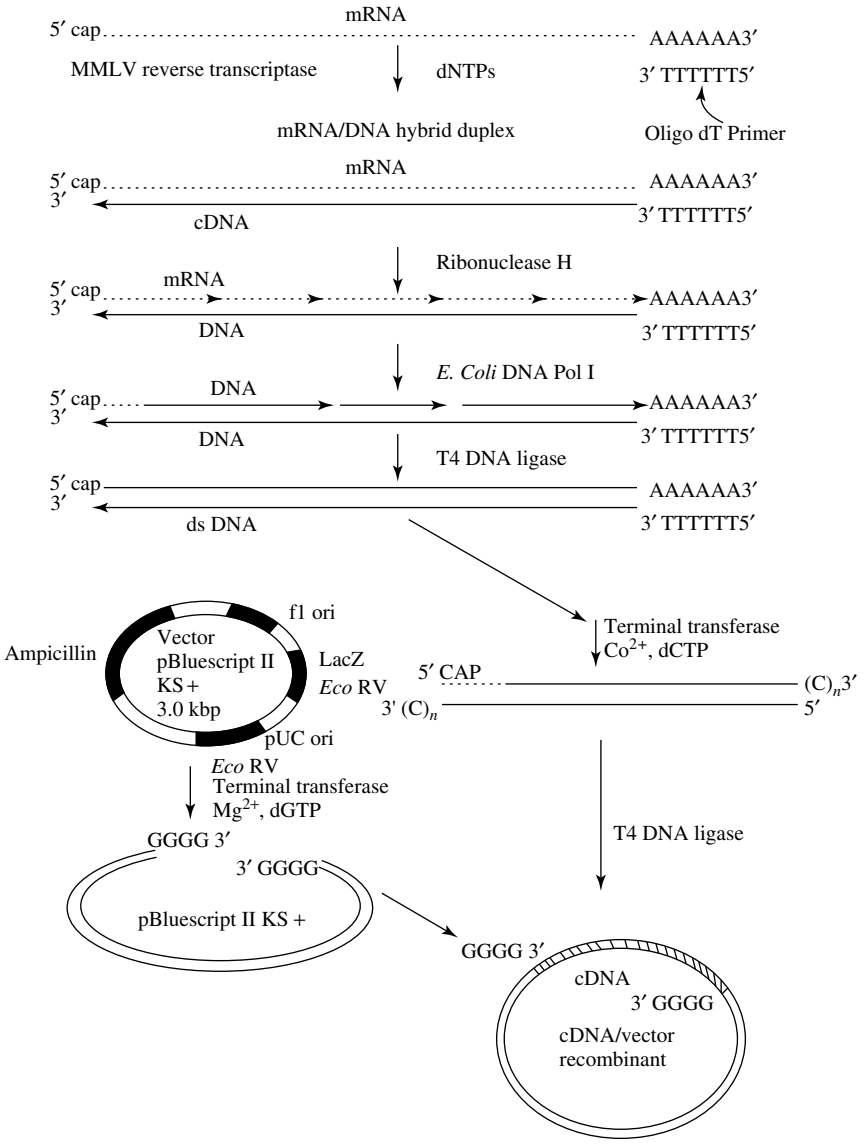

Fig. 2 A general procedure for the construction of cDNA/vector recombinants for cDNA library construction. pBluescript II KS+ is the cloning vector; ''DNA Pol I'' indicates ''DNA Polymerase I;'' ''dNTPs'' indicates ''dATP, dCTP, dGTP and dTTP;'' and ''ds DNA'' indicates ''double strand DNA.''

in combination with the extremely high-efficiency electroporation transformation are becoming the method of choice for cDNA library construction. There are two ways of preparing the synthesized cDNA into clonable cDNA – homopolymeric tailing and linker addition. Homopolymeric tailing is completed by an enzyme called

terminal transferase, which is an unusual DNA polymerase found only in a type of eukaryotic cell called a *prelymphocyte*.

1. In the presence of a divalent cation, terminal transferase catalyzes the addition of dNTPs to the 3′-hydroxyl termini of DNA. In the presence of Mg^{2+}, a purine (G or A) is added, and in the presence of Co^{2+}, a pyrimidine (C or T) is added.
2. Depending on the reaction conditions, anywhere from three to several thousand nucleotides can be added.
3. One nucleotide (e.g. dCTP) is added to the 3′ ends of the ds cDNA using the terminal transferase in the presence of Co^{2+}; the plasmid vector is digested with a restriction enzyme (e.g. *Eco* RV); the complementary nucleotide (e.g. dGTP) is added to the one already added to the cDNA at the 3′ ends of the vector; and it is digested using the terminal transferase in the presence of Mg^{2+}. Now the tailed vector and cDNA are mixed, annealed and ligated into cDNA/vector recombinant DNA (also called ligation mixture). The molar ratio of insert : vector for the ligation is from 8–15 : 1, of which routinely 50 to 95% of the transformants are clones containing recombinant DNA.

Alternatively, ds cDNA can be cloned into a library vector through the addition of ''linkers'' to the ds cDNA. Linkers are short oligonucleotides (~18 to 24 mers), which are typically palindromic and contain a single or repeated restriction endonuclease recognition sequence (e.g. *Eco* RI site). The palindromic nature allows the linker oligonucleotide to self-hybridize to form a blunt-ended duplex. If the ends of the cDNA are blunt, then the linker can be ligated to both ends to introduce terminal restriction cloning sites. The steps of linker addition are as follows:

1. Treat the cDNA with S1 nuclease to remove possible 5′ cap mRNA fragment remaining in cDNA duplex.
2. Convert potential ''ragged'' ends to blunt by treatment with Pol I. The Pol I will fill in 5′ overhangs and chew back 3′ overhangs.
3. Methylate cDNA at the potential internal *Eco* RI sites of the cDNA by treatment with *Eco* RI methylase (plus S-adenosyl methionine).
4. Ligate *Eco* RI-containing linkers to the end-blunted, methylated cDNA using T4 DNA ligase.
5. Cut the linkers with *Eco* RI restriction endonuclease and remove the excess linkers from cDNAs by agarose gel electrophoresis.
6. Ligate cDNA to a cloning vector prepared using *Eco* RI restriction endonuclease, followed by a process called dephosphorylation (see below for vector preparation; see above for the ligation molar ratio of insert : vector = 8–15 : 1).

3.1.3 Transformation of the Recombinant Plasmid into *E. coli*

The procedure of transferring the recombinant plasmid, phage, or cosmid into host cells is called transformation. Before transformation, the host cell must be treated to make the cell competent to accept foreign DNA such as plasmid or cosmid. Although the recombinant DNA can be transformed into the host cells through different methods, we use the electroporation method here as an example due to its simplicity and high transformation efficiency ($>10^{10}$ cfu per μg vector DNA).

1. Make agar plates containing 25 g LB (Luria Broth) base, 15 g agar, appropriate antibiotics, 75 µL of 200 mg mL^{-1} IPTG (isopropylthio-β-D-galactoside) and 3 mL of 20 mg mL^{-1} x-gal (5-bromo-4-chloro-3-indoyl-β-D-galactoside) per liter.
2. Transform the ligated DNA into the *E. coli* strain DH5α electrocompetent cells (Life Technologies) by electroporation using the Cell Porator and Voltage Booster System (Life Technologies) at the following settings:

Cell Porator	*Voltage Booster*
Voltage	400 V
Capacitance	330 µF
Impedance	Low ohms
Charge rate	Fast
Resistance	4 kΩ

3. Collect the cells into 1 mL SOC medium and incubate at 37 °C with shaking at 250 rpm for 1 h to allow the cells to recover and fully develop resistance to the antibiotics.
4. Plate the recovered cells onto the agar plates made at the first step. Incubate at 37 °C for 24 h to allow the colony colors to fully develop. The white clones are the recombinant clones. Titer the transformed cells and calculate the number of clones needed for the cDNA library. cDNA libraries are usually stored in bulk as glycerol stocks. For some special research purposes, the cells are plated on the selective agar medium, and individual clones are arrayed into 96- or 384-well microplates containing freezing medium [LB broth plus 1x freezing buffer (36 mM K_2HPO_4, 13.2 mM KH_2PO_4, 1.7 mM citrate, 0.4 mM $MgSO_4$, 6.8 mM $(NH_4)_2SO_4$, 4.4% (v/v) glycerol) and appropriate antibiotics] and maintained in a −80 °C freezer for long-term storage.

3.1.4 Normalization of the cDNA Library

A fundamental problem in cDNA library construction is the occurrence of redundant sequences. This occurs because mRNA titers and their derived cDNA clones vary over several orders of magnitude in a particular tissue. The range of gene expression may be as high as 200 000 mRNA molecules per cell or as low as <1 per cell on average, with perhaps 30% of the genes expressing at levels of less than 10 mRNA molecules per cell at any given time. This implies that several million clones are needed to have a reasonable chance of finding a specific low-abundance transcript. In large-scale cDNA sequencing for these low-abundance classes, strategies are needed to normalize the cDNA populations. Since the goal is to construct a genome-wide cDNA library and generate as many unique ESTs as possible, normalization is required even though it cannot completely remove the members of gene families. There is, as yet, no single optimal strategy available to maximize the relative abundance of different sequences for normalization of a cDNA library. Each of the different strategies has advantages and disadvantages that also depends on the scope and purpose of a project. Currently, three approaches are used in the cDNA or cDNA library normalization.

1. *Screening with abundant sequences:* The screening probes can either be total cDNA derived from mRNA of the same tissue as the library, or the pools of common-sequence clones (10–20 frequent sequence clones).
2. *Reassociation:* The methods of using several variations of reassociation of single-stranded plasmid preparations

and synthesized insert DNAs could remove the redundant copies of the same clones. This procedure has been used in many plant EST programs including the soybean EST project.

3. *Hybridization to total genomic DNA:* Single-stranded biotin-dUTP labeled genomic DNA has been used to bind to streptavidin-coated magnetic beads to select first-strand cDNA according to relative genome representation. Upon elution, conversion to double-stranded cDNA and cloning, libraries enriched for rarer mRNA sequences are generated.

3.2 Small-insert Genomic DNA Libraries

Currently, the cloning efficiency for the systems such as plasmid, bacteriophage, cosmid, and fosmid is extremely high. Only a small amount of DNA is required when constructing a small-insert genomic DNA library using current transformation technology such as electroporation. A small-insert genomic DNA library can be easily and rapidly generated by a single researcher in any molecular laboratory. Small-insert genomic DNA libraries are essential for genome sequencing, fine-scale mapping and genome analysis. These libraries are often screened by directly screening replicas of randomly plated libraries. Physical shearing and enzymatic partial digestion of source DNA are used to generate clonable DNA fragments for library construction. To construct shotgun libraries from genomic DNA by the physical shearing method, genomic or other source DNA is sonicated from 1 to 20 s with a sonicator on ice and end-repaired by the enzyme Mung Bean Nuclease, followed by size-fractionation on conventional agarose gels. The fractions from 0.4 to 1.2 kb and from 2 to 5 kb are independently cloned into plasmid vectors such as Ready-To-Go TM pUC18 Smal1/BAP (Phamarcia Biotech, #27-5266-01). They are referred to as short-fragment and long-fragment shotgun libraries, respectively. The procedure for construction of a small-insert library by partial digestion is similar to that of large-insert library construction, except that the procedure for preparing the DNA fragments is different. The molar ratio of insert : vector for small-insert library ligation is usually 8–15 : 1, while that for large-insert DNA library construction is usually in the range of 1 : 4–10.

3.3 Large-insert Genomic DNA Libraries

Unlike what is required for the construction of cDNA and small-insert genomic DNA libraries, the *in vitro* construction of large-insert genomic DNA libraries (YAC, P1, BAC, PAC, BIBAC, and PBC) requires the manipulation of extremely long DNA fragments. The most difficult aspect of large-insert recombinant construction is the minimization of random shearing of the genomic DNA used for the insert. Electrophoresis analysis of very large fragments of DNA has been made possible by the advent of PFGE systems in which two separate electric fields are generated across the gel field at different angles, alternating with each other for defined periods of time. One type of PFGE system called the contour clamped homogeneous electric field (CHEF) provides a much more uniform electric field, thereby reducing distortion in DNA migration and improving resolution.

Two systems have been developed for the construction of genomic DNA libraries with insert sizes of 100 kbp or larger: yeast- (YAC) and bacteria (BAC, PAC,

BIBAC, and PBC)-based systems. However, the bacteria-based large-insert library construction system has become more prominent in genome research. The details about YAC and YAC library construction are described in Loehrlein and Ronald's chapter on Yeast artificial chromosome (YAC) construction and applications, pp. 291–302, elsewhere in this series. The construction of bacteria-based large-insert genomic DNA libraries is described in the following sections (Fig. 3):

1. Preparation of HMW genomic DNA in LMP agarose plugs
2. Preparation of vectors
3. Partial digestion of HMW DNA embedded in LMP agarose plugs with a restriction enzyme
4. Size selection of DNA fragments on a CHEF gel
5. Ligation of the HMW DNA fragments into the cloning vector
6. Transformation of the HMW recombinant DNA molecules into *E. coli* host cells
7. Characterization and storage of bacteria-based large-insert genomic DNA libraries

3.3.1 Preparation of HMW Genomic DNA in LMP Agarose Plugs

HMW (>600 kbp) DNA is essential for large-insert genomic DNA library construction. Unlike conventional-size (<200 kbp) DNA preparation, HMW DNA must be protected from physical shearing during preparation. One of the popularly used approaches for doing so is to isolate protoplasts (plants and fungi), cells (animals and microbes), or nuclei (plants, animals, and insects), and then embed them in LMP agarose in the form of plugs or microbeads. The cells are lysed and the DNA is purified in the LMP agarose plugs or microbeads. The resulting HMW DNA is carefully manipulated in LMP agarose plugs or microbeads. Since the preparation of HMW DNA from nuclei is straightforward, it results in low contamination with cytoplast DNA, and is economical and suitable for the preparation of HMW DNA from a wide variety of plant and animal species, the nuclei method is widely used for the preparation of HMW DNA in plants and animals. Here we introduce several procedures for preparation of HMW DNA from plants, animals, insects, and fungi.

3.3.1.1 Preparation of HMW nuclear DNA from plants

Plant materials Plant leaves or whole plants of divergent species, including grasses, legumes, vegetables, and trees, can be used as materials for preparation of HMW DNA by this method. The tissues can be either frozen in liquid nitrogen and stored at −80 °C or kept fresh on ice before use.

Reagents

10 x homogenization buffer (HB) stock: 0.1 M Trizma base, 0.8 M KCl, 0.1 M EDTA, 10 mM spermidine, 10 mM spermine, adjust pH from 9.4 to 9.5 with NaOH. The stock is stored at 4 °C.

1 x HB: A suitable amount of sucrose is mixed with a suitable volume of 10 x HB stock. The final concentration of sucrose is 0.5 M and HB stock is 1 x. The resultant 1 x HB is stored at 4 °C. Before use, β-mercaptoethanol is added to 0.15%.

20% Triton X-100 1 x HB: Triton X-100 is mixed with 1 x HB without β-mercaptoethanol to 20%. The solution is stored at 4 °C.

Wash Buffer (1 x HB plus 0.5% Triton X-100): The buffer is prepared by mixing

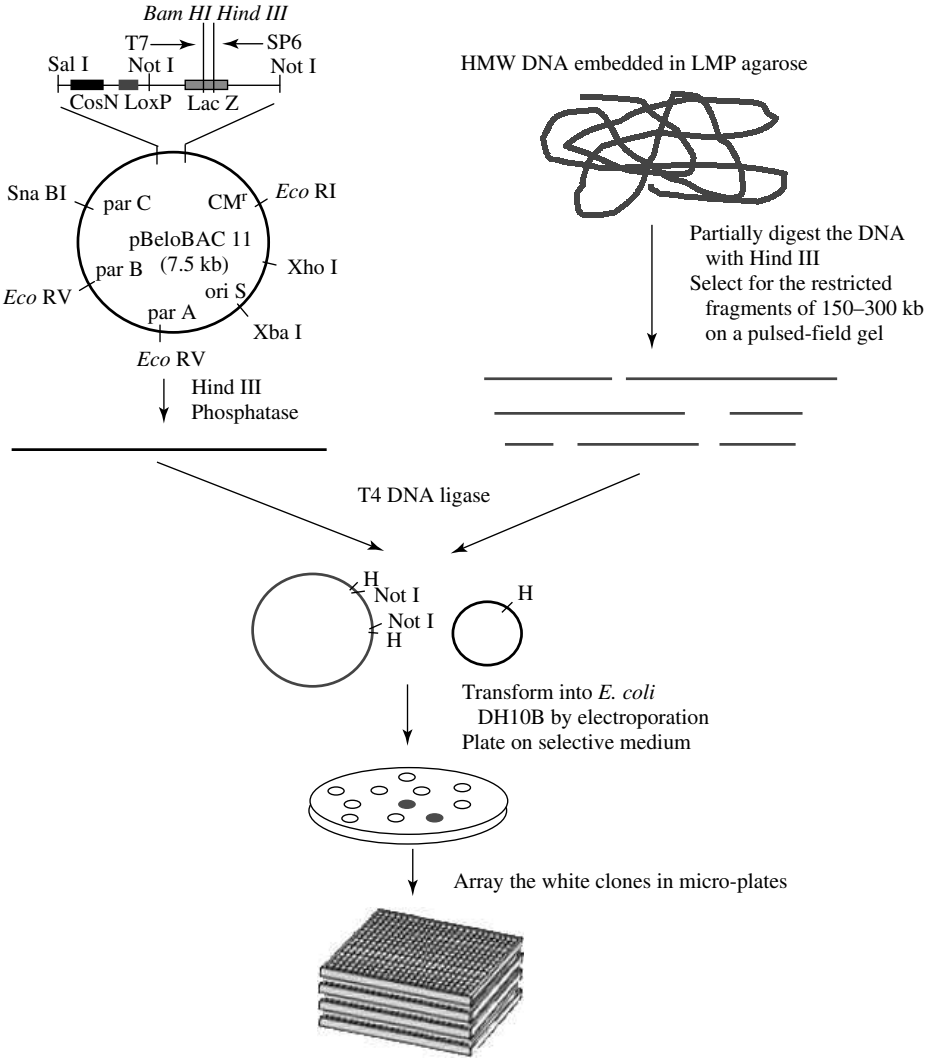

Fig. 3 A general procedure for construction of bacteria-based large-insert, ordered genomic DNA libraries. The bacteria-based large-insert genomic DNA libraries are referred to as BAC, PAC, BIBAC, and PBC libraries. pBeloBAC11 is the cloning vector with two cloning sites, *Bam* HI and *Hind* III (bold). In the procedure, *Hind* III is used for the library construction, and the colorless (white) clones are the clones containing inserts (recombinants).

1 x HB without β-mercaptoethanol with 20% Triton X-l00 in 1 x HB and stored at 4 °C. Before use, β-mercaptoethanol is added to 0.15%.

Lysis buffer: 0.5 M EDTA; pH 9.0 to 9.3, 1% sodium lauryl sarcosine, and 0.1 to 0.5 mg mL^{-1} proteinase K. The proteinase K powder is added just before use.

Procedure

1. Grind about 50 g of the tissue into fine powder in liquid nitrogen with a mortar and pestle, and immediately transfer the powder into an ice-cold 1000-mL beaker containing 800 to 1000 mL ice-cold 1 x HB plus 0.15% β-mercaptoethanol and 0.5% Triton X-100. Gently swirl the contents with a magnetic stir bar for 10 min on ice and filter into six ice-cold 250-mL centrifuge bottles through two layers of cheesecloth and one layer of miracloth by squeezing with gloved hands.
2. Pellet the homogenate by centrifugation with fixed-angle rotor at 1800 g at 4 °C for 20 min, discard the supernatant fluid, and add approximately 1 mL of ice-cold wash buffer to each bottle. Gently resuspend the pellet with the assistance of a small paintbrush soaked in ice-cold wash buffer, combine the resuspended nuclei from all bottles into a 40-mL centrifuge tube and, finally, fill the tube with ice-cold wash buffer. If particulate matter remains in the suspension, filter the resuspended nuclei into the 40-mL centrifuge tube through two layers of miracloth by gravity, centrifuge the contents at 57 g, 4 °C for 2 min to remove intact cells and tissue residues, and transfer the supernatant fluid into a fresh centrifuge tube. Pellet the nuclei by centrifugation at 1800 g, 4 °C for 15 min in a swinging bucket centrifuge.
3. Wash the pellet 1 to 3 additional times by resuspension in wash buffer using a paintbrush followed by centrifugation at 1800 g, 4 °C for 15 min. Note that this step is necessary to minimize the contamination of cytoplast organelles in the nuclei. After the final wash, resuspend the pelleted nuclei in a small amount (about 1 mL) of 1 x HB without β-mercaptoethanol, count the nuclei, if possible, under the contrast phase of a microscope, bring to approximately 5×10^7 nuclei mL^{-1} with addition of the 1 x HB without β-mercaptoethanol, and store on ice. The concentration of nuclei can also be estimated empirically, a concentration of nuclei that is just transparent under light is estimated to be $5–10 \times 10^7$ nuclei mL^{-1}. The concentration of nuclei varies, depending on the genome sizes of different species. In general, 5 to 10 µg DNA of 100-µL plug are suitable for large-insert DNA library construction.
4. Prepare 10 mL of 1% LMP agarose in 1 x HB without β-mercaptoethanol and Triton X-100, cool down to 45 °C and maintain in a 45 °C water bath before use. Prewarm the nuclei to 45 °C in a 45 °C water bath (about 5 min), mix with an equal volume of the prewarmed 1% LMP agarose in 1 x HB without β-mercaptoethanol and Triton X-100 using a cut-off pipette tip. Aliquot the mixture into ice-cold plug molds on ice with the same pipette tip, at 100 µL per plug. When the agarose is completely solidified, transfer the plugs into 5 to 10 volumes of lysis buffer. Incubate the agarose plugs in the lysis buffer for 24 to 48 h at 50 °C with gentle shaking.
5. Wash the plugs once in 0.05 M EDTA, pH 8.0 for 1 h on ice, and store in 0.05 M EDTA, pH 8.0, at 4 °C. The DNA at this step can be stored at 4 °C for 1 year without significant degradation.

3.3.1.2 **Preparation of HMW DNA from animals** Preparation of HMW DNA from animals is much easier and simpler

than the preparation of HMW DNA from plants. Animal cells can be directly embedded into LMP agarose plugs after briefly washing. Although the nuclei of animal cells can be used, the whole cells are frequently used for HMW DNA preparation. Here, the preparation of chicken HMW DNA plugs is used as an example.

Materials Whole chicken blood cells collected in heparinized tubes are used.

Procedure

1. Centrifuge the chicken blood cells at 1000 g, room temperature for 5 min, discard the supernatant and resuspend the cells in the phosphate-buffered saline (PBS) buffer (138 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 1.8 mM NaH_2PO_4, pH 7.4). Repeat this 2 to 3 times and then bring the concentration of cells to $5–10 \times 10^7$ cells mL^{-1}.
2. Prewarm the cell suspensions at 45 °C for 5 min in a water bath, and mix with equal volume of 1% LMP agarose in PBS molten and maintained in a 45 °C water bath. Aliquot into ice-cold 100-µL plug molds with a pipette using a cut tip and keep the molds on ice for 15 min to allow the plugs to completely solidify. Transfer the plugs into the lysis buffer (0.5 M EDTA, pH 9.0, 1% lauryl sarcosine, and 0.5 to 1 mg mL^{-1} proteinase K) at approximately 1 mL lysis buffer per 100-µL plug. Incubate at 50 °C with gentle shaking for 24 to 48 h.
3. Wash the plugs once in 0.05 M EDTA, pH 8.0 for 1 h on ice, and store in 0.05 M EDTA, pH 8.0, at 4 °C. The DNA at this step can be stored at 4 °C for 1 year without significant degradation.

3.3.1.3 **Preparation of HMW DNA from insects** Preparation of HMW DNA from insects is similar to those from plants and animals. Here, the preparation of mosquito and worm HMW DNA are used as examples.

Mosquito

Materials The L1 larvae of mosquito are used as materials. Either fresh or liquid nitrogen-frozen L1 larvae are suitable for preparation of HMW DNA.

Procedure

1. Grind the fresh or frozen L1 larvae into fine powder in liquid nitrogen with a mortar and pestle, and transfer the powder into the suspension solution (100 mM NaCl, 200 mM sucrose and 10 mM EDTA, pH 8.0), or add 10 to 20 mL of the suspension solution into the mortar and incubate at room temperature until the frozen sample and solution just melt. Filter the cell suspensions through 1 to 2 layers of miracloth into a centrifuge tube on ice to remove the large pieces of cell debris and spin at 2000 g, 4 °C for 10 min to collect the cells. Discard the supernatant and resuspend the cells in about 0.5 to 1.0 mL of the suspension solution, depending on the amount of the sample used. From 500 mg fresh weight of mosquito larvae, resuspend the cell pellet in about 1.0 mL of the suspension solution and make about 20 100-µL plugs.
2. Prewarm the cell suspensions at 45 °C for 5 min in a water bath, and mix with an equal volume of molten

1% LMP agarose in the suspension buffer maintained in a 45 °C water bath. Aliquot into ice-cold 100-μL plug molds using a cut pipette tip and keep the molds on ice for 15 min to allow the plugs to completely solidify. Transfer the plugs into the lysis buffer (0.5 M EDTA, pH 9.0, 1% lauryl sarcosine, and 0.5 to 1 mg mL^{-1} proteinase K) at approximately 1 mL lysis buffer per 100-μL plug. Incubate at 50 °C with gentle shaking for 24 to 48 h.
3. Wash the plugs once in 0.05 M EDTA, pH 8.0 for 1 h on ice, and store in 0.05 M EDTA, pH 8.0, at 4 °C. The DNA at this step can be stored at 4 °C for 1 year without significant degradation.

Worms

Materials Depending on species, cells, tissues, or whole body (larvae, pupae, or adults) may be used as materials.

Procedure

1. Grind the fresh or frozen tissues or entire body into fine powder in liquid nitrogen with a mortar and pestle, transfer the powder into ice-cold STE buffer (0.1 M NaCl, 10 mM Tris-HCl, 10 mM EDTA, pH 8.0) with 30 mM β-mercaptoethanol and kept on ice for 10 min with gentle stirring. Filter the cell suspension through 1 to 2 layers of miracloth into a centrifuge tube on ice to remove the large pieces of cell debris and spin at 5000 rpm, 4 °C for 10 min to pellet the cells. Wash the cells in the STE buffer without β-mercaptoethanol once and collect the cells as above. Discard the supernatant and resuspend the cells in 1 to 2 mL STE buffer (without β-mercaptoethanol) per gram of the tissues or whole bodies. This allows the making of 20 to 40 of the 100-μL LMP plugs.
2. Prewarm the cell suspensions at 45 °C for 5 min in a water bath, and mix with an equal volume of molten 1% LMP agarose in the STE buffer maintained in a 45 °C water bath. Aliquot into ice-cold 100-μL plug molds using a cut pipette tip and keep the molds on ice for 15 min to allow the plugs to completely solidify. Transfer the plugs into the lysis buffer (0.5 M EDTA, pH 9.0, 1% lauryl sarcosine, and 0.5 to 1 mg mL^{-1} proteinase K) at approximately 1 mL lysis buffer per 100-μL plug. Incubate at 50 °C with gentle shaking for 24 to 48 h.
3. Wash the plugs once in 0.05 M EDTA, pH 8.0 for 1 h on ice, and store in 0.05 M EDTA, pH 8.0, at 4 °C. The DNA at this step can be stored at 4 °C for 1 year without significant degradation.

3.3.1.4 **Preparation of HMW DNA from fungi** Preparation of HMW DNA from fungi is similar to that from plant protoplasts. Fungal spheroplasts can be generated by treatment of cultured fungal cells with Novozym and then washed briefly.

Materials Cultured cells are used as materials.

Procedure

1. Collect the fungal cell culture by centrifugation at 1000 g, room temperature for 4 min. Wash the cells in 10 mL 1 M sorbitol per gram of fungi, resuspend in 10 mL SCE (1 M sorbitol, 20 mM sodium citrate pH 5.8,

10 mM EDTA) and add Novozym to 10 mg/mg cells. The mixture is incubated with shaking at 100 rpm for 90 min at room temperature. Harvest the spheroplasts by filtering successively through cheesecloth and Nytex nylon mesh that has a 25-μ pore size, followed by pelleting at 2000 g, 4 °C for 10 min. Wash the spheroplasts twice with 1 M sorbitol and then resuspend in 1 M sorbitol at about 3×10^9 cells mL^{-1} to obtain about 6 μg DNA in a 100-μL plug.

2. Prewarm the cell suspensions at 45 °C for 5 min in a water bath, and mix with an equal volume of molten 1% LMP agarose in the SCE buffer maintained in a 45 °C water bath. Aliquot into ice-cold 100-μL plug molds using a cut pipette tip and keep the molds on ice for 15 min to allow the plugs to completely solidify. Transfer the plugs into the lysis buffer (0.5 M EDTA, pH 9.0, 1% lauryl sarcosine, and 0.5–1 mg mL^{-1} proteinase K) at approximately 1 mL lysis buffer per 100-μL plug. Incubate at 50 °C with gentle shaking for 24 to 48 h.
3. Wash the plugs once in 0.05 M EDTA, pH 8.0 for 1 h on ice, and store in 0.05 M EDTA, pH8.0, at 4 °C. The DNA at this step can be stored at 4 °C for 1 year without significant degradation.

3.3.2 Preparation of Vectors

Several plasmid-based vectors, including BAC, PAC, BIBAC, and PBC, have been widely used for bacteria-based large-insert genomic DNA library construction (Table 1). Preparation of the vectors is one of the most critical steps for successful construction of large-insert DNA libraries. The vector DNA to be used for library construction must be very pure, completely digested (but not overdigested) and completely dephosphorylated (>95% recombinant clones in a ligation test). The vector DNA to be used for library construction is isolated and purified from 1 to 2 L overnight culture by the alkaline lysis method, followed by two rounds of cesium chloride/ethidium bromide gradient ultra-centrifugations. Below is a widely used procedure for the preparation of vectors for library construction, including cDNA, small-insert, and large-insert genomic DNA libraries.

1. Completely digest 20 μg of the vector DNA using an appropriate restriction enzyme (here, a 5′-overhang restriction enzyme is used as an example) and check the digestion on a 1% agarose gel to ensure that the digestion is complete. Note that overdigestion may lead to an increase of the percentage of clones with no inserts (insert-empty clones).
2. Extract the digest with an equal volume of saturated phenol/chloroform (1 : 1), and spin at 10 000 rpm, room temperature for 5 min. Precipitate the DNA by adding 1/10 volume of 3 M NaAC, pH 5.2 and 2 volumes of 100% ethanol and incubating at −80 °C for 10 min, followed by centrifugation at 10 000 rpm for 15 min. Discard the supernatant fluid, wash the pellet carefully with 70% ethanol, air-dry, dissolve in 100 μL H_2O, and measure the concentration of the DNA using λDNA of known concentration on a 1% agarose gel.
3. Dephosphorylate the linearized vector with calf intestinal alkaline phosphatase (CIAP) at 37 °C for 30 min, at a ratio of 1.0 unit/pmole (3.89 units of CIAP/10 μg DNA for pBeloBAC11, 1.23 units of CIAP/10 μg DNA for BIBAC2, or 1.0 units of CIAP/10 μg

DNA for pCLD04541). Stop the reaction immediately by adding 4 µL 0.5 M EDTA, pH 8.0, 20 µL 10% SDS and 40 µL of 1 mg mL^{-1} proteinase K in cold TE to the tube, followed by incubation at 56 °C for 30 min.

4. Cool down to room temperature, extract once with an equal volume of saturated phenol and then once with an equal volume of saturated phenol/chloroform/iso-amyl alcohol (25 : 24 : 1). Precipitate the DNA by adding 1/10 volume of 3 M NaAC, pH 7.0 and 2 volumes of 100% ethanol and incubating at −80 °C for 10 min, followed by centrifugation at 10 000 rpm for 15 min.
5. Discard the supernatant fluid, wash the pellet carefully with 70% ethanol, air-dry, dissolve in 200 µL H_2O, and measure the concentration of the DNA using λDNA of known concentration on a 1% agarose gel. Adjust the concentration of the DNA to 10 ng/µL for pBeloBAC11, and to 40 ng μL^{-1} for BIBAC2 or pCLD04541, aliquot the DNA and store in a −20 °C freezer. The vector DNA in the −20 °C freezer is good for cloning for at least three months. To ensure that the vector is properly dephosphorylated, ligate the vector DNA into the λDNA digested with the same restriction enzyme. When a molar rate of 4 vector : 1 digested λDNA is used and the ligation mixture is transformed into *E. coli* DH10 cells by electroporation, the percentage of recombinant (white) clones should be greater than 95%.

3.3.3 Partial Digestion of HMW DNA Embedded in LMP Agarose Plugs with a Restriction Enzyme

Before use, the LMP agarose plugs containing HMW DNA should be washed 3 times for 1 h each in 10 to 20 volumes of ice-cold TE (10 mM Tris-HCl, pH 8.0, 1 mM EDTA, pH 8.0) plus 0.1 mM phenylmethyl sulfonyl fluoride (PMSF), and 3 times for 1 h each in 10 to 20 volumes of ice-cold TE on ice. As described above, several methods have been used to partially digest the HMW DNA embedded in LMP agarose plugs with a restriction enzyme. Described below is the partial digestion strategy of varying the concentration of the enzyme used at a fixed digestion time. A series of small pilot digestions is commonly carried out to determine the optimal concentration range of the enzyme required to generate DNA fragments desirable for library construction.

1. Slice each LMP agarose plug containing HMW DNA into nine equal-sized pieces per 100-µL plug, and equilibrate the pieces in the restriction-enzyme reaction buffer containing 2 mM spermidine and 1 mM dithiothreitol (DTT) at 3 mL 100-μL^{-1} plug, on ice for 1 h, changing the buffer once. Then, transfer three plug slices each into 1.5-mL microtubes containing 170 µL reaction buffer with 0.5 mg ml^{-1} BSA, 2 mM spermidine, 1 mM DTT, and a concentration series of the enzyme (0–20 units/tube). Incubate on ice for 60 to 100 min, depending upon the compactness of the HMW DNA plugs, to allow the enzyme access to the DNA in the agarose.
2. Transfer the digestion reactions into a 37 °C water bath and incubate for exactly 8 min. Immediately transfer the reactions onto ice and then stop them by adding 1/10 volume of 0.5 M EDTA, pH 8.0. Keep the reactions on ice.
3. Analyze the partial digestions by loading the plug slices on a 1% agarose

gel in 0.5 x TBE and subjecting to the PFGE using the CHEF DRIII under the following conditions: 11 °C (setting for the cooler), 80 (pump setting), 120° angle, 6 V cm^{-1} and 50-s switch time for 18 h. The partial digestion condition that generates restricted fragments in a size range of 100 to 400 kbp is selected for large-scale partial digestion for the construction of DNA libraries with an average insert size of about 150 kbp.

4. Perform large-scale partial digestion (usually 6–10 100-µL plugs) using the optimal digestion conditions determined above.

3.3.4 Size Selection of DNA Fragments on a CHEF Gel

After partial digestion, the DNA fragments must be selected to obtain the fragments that are desirable in size range for library construction and to remove the smaller fragments that can compete more effectively for vector ends. To this end, PFGE has been widely used for size selection; almost all YAC and bacteria-based large-insert DNA libraries constructed to date have used this method for size selection. Furthermore, to maximize the removal of the small DNA fragments, many scientists perform two rounds of size selection by PFGE.

1. *First size selection*: Prepare a 1% agarose CHEF gel in 0.5 x TBE with a sample trough at the top portion of the gel and 2 L of 0.5 x TBE running buffer, and precool the buffer to 11 °C in the electrophoresis chamber. Load the plug slices containing the partially digested DNA into the sample trough, and size markers (lambda concatemers and/or yeast chromosomes) in the wells on both sides of the trough. Seal the sample trough and marker wells with 1% molten agarose gel. Run the CHEF gel using the CHEF DRIII system at 6.0 V cm^{-1}, 11 °C, 120° angle, and 90-s switch time in 0.5 x TBE for 16 h. Cut both the sides of the gel that contain the size markers and the edge of the DNA sample with a clean microscope glass slide coverslip and keep the center of the gel on ice. Stain and photograph the gel pieces containing the samples adjacent to the size markers alongside a scale ruler. Using the photograph as reference, locate the gel zone containing the DNA fragments ranging from 100 to 400 kbp in the unstained portion of the gel, excise it, and cut it into three sections horizontally, 100 to 200 kb, 200 to 300 kb and 300 to 400 kb. Recover the size-selected DNA in each gel section by electroelution in a dialysis tube (1/4 in in diameter and molecular weight exclusion limit = 12 000–14 000 Da) in 0.5 x TBE using the CHEF DRIII at 6 V cm^{-1}, 11 °C, and 35-s switch time for 4 h, followed by reversing the polarity of the current for 60 s. The DNA fragments can be used for ligation and library construction after dialysis in 0.5 x TE (see below), or are carefully transferred from the dialysis tubing to a microfuge tube with a wide-bore pipette tip for the second size selection.
2. *Second size selection*: Prepare a 1% agarose CHEF gel in 0.5 x TBE with a sample trough at the top portion of the gel and 2 L of 0.5 x TBE running buffer, and precool the buffer to 11 °C in the electrophoresis chamber. Load size markers on both sides of the sample trough, seal the marker wells with 1% molten agarose gel, and place in the electrophoresis chamber containing the 0.5 x TBE buffer. Mix

the DNA fragments from the first size selection with the gel-loading dye by inverting the tube gently, and load into the sample trough. Run the CHEF gel at 4 V cm^{-1}, 11 °C and 5-s switch time in 0.5 x TBE for 6 to 8 h. Locate and excise the gel zone containing the compressed DNA fragments, and electroelute the DNA from the gel as above.

3. Dialyze the DNA fragments electroeluted from the gel in the same dialysis tubing against 1 L of 0.5 x TE for 3 h at 4 °C with one change of 0.5 x TE every hour. Carefully collect the DNA from the dialysis tubing to a 1.5-mL microtube with a wide-bore pipette tip for ligation and library construction. The immediate ligation of the DNA into a vector following dialysis often gives a much better result.

3.3.5 Ligation of the HMW DNA Fragments into the Cloning Vector

The concentration of the DNA collected from the second size selection is routinely 1 to 8 ng μL^{-1}. The concentration of the DNA needs to be estimated before preparing the ligation reactions.

1. Estimate the concentration of the insert DNA on a 1% conventional agarose minigel using the known concentration of λDNA as standard.
2. Set up the ligation using the following criteria: Molar ratio of vector : insert = 4–10 : 1, the final concentration of insert DNA in the ligation mixture = 1–2 ng μL^{-1} and T4 DNA ligase = 1 unit per 50 µL ligation. To control the ratio between recombinant and nonrecombinant clones in the transformants, the molar ratio of vector:insert can be adjusted, with a smaller ratio for a higher recombinant/nonrecombinant clone ratio.
3. Incubate the ligation at 16 °C for 6 to 10 h. The ligation can immediately be used for transformation, or aliquoted and stored in a −20 °C, non frost-free freezer. The ligation can be stored for several months without significant problems. Although it was observed that the storage of the ligated DNA might slightly reduce the transformation efficiency, it did not significantly reduce the insert sizes of the clones.

3.3.6 Transformation of the HMW Recombinant DNA Molecules into *E. coli* Host Cells

Although recombinant DNA can be transformed into host cells through several methods, almost all existing bacteria-based large-insert genomic DNA libraries, including BAC, PAC, BIBAC, and PBC, were constructed using the electroporation method due to its extremely high transformation efficiency. Similarly, almost all existing bacteria-based large-insert genomic DNA libraries are hosted in *E. coli* strain DH10B and its derivatives. This is because it has been proven that the large-insert clones can be stably maintained and propagated in these strains; other strains may not be capable of stably maintaining and propagating large-insert genomic DNA clones in their cells.

1. Mix 1 to 2 µL of the ligation mixture with 20 µL of *E. coli* DH10B electroporation-competent cells and transform into the cells using the Cell Porator and Voltage Booster electroporation system (Life Technology) at the following settings:

Cell Porator	*Voltage Booster*
Voltage	350–400 V
Capacitance	330 µF
Impedance	Low ohms

Charge rate	Fast
Resistance	4 kΩ

2. Transfer the electroporated cells in 1 ml of SOC medium and incubate at 37 °C, 250 rpm for 1 h to allow the antibiotics-resistant gene to be fully expressed, and then plate onto LB agar medium containing appropriate antibiotics and/or amendments for transformant and recombinant selection. For the vectors, such as pBeloBAC 11 and pCLD04541, that use *Lac*Z gene for recombinant selection, incubate at 37 °C for 36 h to allow the colony color (blue) to fully develop, whereas for the vectors, such as BIBAC2, that use the *Sac*B gene for recombinant selection, incubate at 37 °C for 20 h. The colorless (white) colonies constructed with the *Lac*Z gene-containing vectors are expected to contain inserts (recombinants), whereas all of the clones of the *Sac*B gene-containing vectors growing on the selective medium are expected to contain inserts.

3.3.7 Characterization and Storage of Bacteria-based Large-insert Genomic DNA Libraries

Analysis of the clones resulting from a particular ligation is essential before large-scale transformation and library assembly are undertaken. The parameters usually used for this purpose include average insert size and distribution, and the percentage of empty clones. In general, a large-insert genomic DNA library such as is desirable for genome research should have a large average insert size (≥150 kbp), a low percentage of insert-empty clones (≤5%) and a reasonable distribution of clones in insert sizes (providing a better genome coverage). Therefore, at least 100 randomly selected clones obtained from each ligation should be analyzed.

1. Inoculate the recombinant clones on the selective medium in 5 mL of LB medium with appropriate antibiotics and incubate at 37 °C with shaking at 250 rpm overnight. Isolate DNA using the alkaline lysis method, digest with *Not* I, a rare cutting enzyme, and run on a 1% pulsed-field gel in 0.5 x TBE at 6 V cm^{-1}, 11 °C, 5-s initial switch time and 15-s final switch time with a linear ramp, for 16 h. Stain the gel with ethidium bromide, photograph and estimate the insert size of each clone by adding the sizes of all DNA fragments derived from the clone insert and the number of clones with no inserts.
2. Select the ligation that gives the largest insert sizes, fewer insert-empty clones, and higher transformation efficiency for large-scale transformation and library assembly. Array the recombinant clones into 384-well microtiter plates containing 50 µL of freezing medium (see above) per well with appropriate antibiotics, grow at 37 °C overnight and store at −80 °C for long-term maintenance. Usually, the library is replicated and stored in separate −80 °C freezers to guard against unforeseen disasters.

4 Applications of DNA Libraries

DNA libraries are indispensable and crucial tools for molecular biology research. They have been used in every aspect of molecular biology. Summarized below are a few examples of their applications.

4.1 Gene Discovery, Expression, and Function Studies

cDNA libraries have been essential resources for gene discovery, expression monitoring, and function analysis. cDNA sequence tags, popularly known as ESTs, can be used not only for the analysis of gene structure, expression, and function but also for the study of genome composition, organization, and structure. Projects for developing ESTs for a large number of genes have emerged in the past few years as one of the approaches to rapid gene discovery. In this approach, a large number of cloned cDNAs are randomly chosen from the cDNA libraries constructed from different tissues or treatments, and sequenced from one or both ends of the clone inserts. The nucleotide sequences and translations of the ESTs are used as tags of the corresponding genes to compare with the sequences of known functions available in the public databases for identification of homologs and to provide useful information for gene identification.

Currently, a few genomes of model plant and animal species, such as *Arabidopsis, Drosophila*, rice, mosquito, and human have been sequenced. The availability of these sequences provides us with a detailed view of the gene content and genome organization of the species. Yet, the degree to which the gene content, gene number, and genome organization are conserved among related species remains unresolved. It will require the sequencing of genomes from many other species to answer these questions. However, because there are so many species with relatively larger genome sizes compared with those of model genomes, and also considering the associated high cost of sequencing, it is unlikely that we will have the full genomic sequences for many other species in the near future. Large-scale EST sequencing thus provides a less expensive alternative approach, which can reveal a substantial portion of the expressed genes of a genome at a fraction of the cost of a genomic sequencing project. Therefore, extensive EST projects have been performed or are under way in a wide variety of animal and plant species. With all of these EST and genomic sequencing projects, it is anticipated that once most genes are identified and their clones become available, the process of gene identification and characterization will be accelerated several-fold.

There are tens of thousands of genes and their products (e.g. RNA and proteins) in a given organism that function in a complicated and orchestrated way to create the mystery of life. However, classic procedures in molecular biology generally work in a ''one gene one experiment'' fashion, which means that the throughput is very limited and the ''whole picture'' of gene function is difficult to obtain. In the past few years, a new technology, now known as DNA microarrays or DNA chips, has been invented, in which a large number of DNA clones (e.g. cDNA clones or synthesized oligonucleotides) are arrayed by high-speed robotics on glass slides or nylon substrates, and fluorescently labeled target nucleic acid samples are used to hybridize the DNA microarray, allowing high-throughput study of gene expression, gene function, and gene identity. This technique also promises to monitor genes at the whole-genome level even on a single chip so that researchers can have a better picture of the interactions among thousands of genes simultaneously.

4.2 Gene Mapping and Cloning

Depending on the type and amount of information available for target genes, DNA libraries can be used for gene mapping and cloning in different ways. When the information regarding the function of a target gene and its protein product is available, a method called functional cloning could be used. Knowledge of gene function assists investigators to develop strategies to purify the gene product and link it with a phenotype, develop antibodies, derive partial amino acid sequence, and then identify cDNA clones containing the target gene by screening an expression cDNA library using antibodies or degenerate oligonucleotides derived from the protein sequence. When a cDNA clone is identified, isolated, and sequenced for verification that it corresponds to the desired gene, it is then used as a probe to screen a genomic library and thereby to isolate its cognate gene. The cDNA clone could also be used for studying the gene expression in different cell types, tissues, and developmental stages.

The candidate gene method is another approach to isolating a gene of interest from a DNA library based on the existing information about the gene. This method is based on a survey of previously identified genes that seem to perform the same function altered in a mutant. Clone(s) for the candidate gene can be isolated from a DNA library by screening the library using the candidate gene previously identified from other species as a probe. The genetic position of the candidate gene and mutation analysis can be further used to confirm the candidacy of the gene.

On the other hand, there is no available prior knowledge of RNA and protein products for many genes. These genes are known only by their phenotypes. To clone such genes, an approach named *positional cloning* or *map-based cloning* has been developed. By using a genetic cross, a phenotype can be assigned to a map interval by identifying two flanking genetic markers. Once the chromosomal localization of the gene locus has been established with DNA markers, genomic DNA libraries, particularly large-insert DNA libraries, for example, BAC or YAC libraries, are screened with the DNA markers to identify overlapping genomic DNA clones covering the marker locus. The clones are then analyzed, assembled into an overlapping clone contig and mapped against the target gene. If the contig does not cover the locus of the target gene, new probes are developed from the ends of the contig and used to rescreen the library. The new clones are used to extend the contig and are mapped against the target gene. Using this strategy of chromosome walking, the clone(s) containing the target gene can be isolated. Once a clone containing the target gene is identified, it can be transformed into a mutant of the gene. The genetic complementation of the clone to the mutant phenotype will indicate that the clone contains the target gene.

The completion of major sequencing efforts, such as in *Arabidopsis* and human, promises to alter the classical paradigm by providing the identity and syntenic relationships between the genes. These new tools and knowledge will further accelerate the process of novel gene identification.

4.3 Genome Physical Mapping

DNA libraries, especially large-insert, ordered DNA libraries, are essential sources

for genome physical mapping. Clone (P1, BAC, BIBAC, PAC, PBC, and YAC)-based physical maps are the centerpiece of genomics research. They are essential not only for an efficient and thorough approach to large-scale genome sequencing but also for performing efficient map-based cloning and associating candidate genes with biological, medical, or agronomic traits. Several methods have been developed and used to construct genome-wide physical maps from large-insert genomic DNA libraries. These include DNA marker-based chromosome landing, random DNA clone fingerprinting and contig assembly, and BAC end sequencing and fingerprint analysis.

DNA marker-based chromosome landing is a hybridization- and/or PCR-based strategy for genome physical mapping, depending on the types of DNA markers to be used for landing the large-insert clones of the source library to the target linkage map (see below). DNA markers are selected from a molecular genetic linkage map and used as probes or PCR primers to screen the large-insert source library. Overlapping clones are assembled into contigs according to the probes to which they hybridize, or the primer pairs with which they produce PCR products. The contigs are extended and anchored to the genetic linkage map according to the position of the DNA markers on the genetic map. This physical mapping strategy was first used in the development of YAC-based physical maps of the human, mouse, rice and *Arabidopsis thaliana* genomes, and recently, in the development of the BAC-based physical map of the euchromatic portion of the *Drosophila* genome.

If the markers are PCR-based, such as sequence-tagged site (STS) and simple sequence repeats (SSRs), the large-insert clones of the source library are anchored to the genetic map by screening the source library with PCR, in which the library is fabricated into DNA pools, including multiple-plate superpools, single-plate pools, column pools and row pools. Alternatively, the synthetic oligos or PCR products of the STSs and SSRs can also be used as hybridization probes to land large-insert clones to the target linkage map by the hybridization-based strategy. The sequences of the STSs and SSRs are helpful for anchoring sequence assemblies to chromosomes (linkage groups) through the bioinformatics approach. However, if the DNA markers are hybridization-based, such as RFLPs (restriction fragment length polymorphisms) and synthetic Overgos, the large-insert clones of the source library are anchored to the genetic linkage map by screening the source library with hybridization probes. In this method, the library is robotically gridded onto high-density colony filters.

A significant advantage of this physical mapping strategy is the development and integration of the physical map with linkage genetic maps in the same process. The integration of the physical map with a genetic map will associate the large-insert clones of the map with useful traits, which will greatly expedite isolation of the genes by positional cloning. However, it is a prerequisite to have a high-density, evenly distributed DNA marker genetic map and a genomic DNA library of very large inserts in order to develop a whole-genome physical map with this strategy. First of all, although high-density DNA marker maps have been developed for the genomes of human and several model species, they are not available for many of the plant and animal species of economic importance. Second, bacteria-based large-insert clones have much smaller insert sizes than YACs. The smaller insert sizes

of the bacteria-based large-insert clones require highly saturated DNA marker maps for the development of a BAC-based physical map using the DNA marker-based chromosome landing strategy.

Random DNA clone fingerprinting and contig assembly is a restriction fragment fingerprint-based strategy for genome physical mapping. This strategy is based on the hypothesis that the clones derived from the same regions of a genome share similar restriction patterns (a large number of common bands). The restriction pattern of a clone is designated as the ''fingerprint'' of the clone. DNAs are purified from random clones of the source genomic DNA library and digested with one or more restriction enzymes. The restricted fragments are either directly fractionated on gel matrices, or end-labeled and then fractionated on gel matrices to generate fingerprints for each clone. The fingerprints of the clones are visualized and digitized using computers. Overlapping clones are assembled into contigs according to the similarity of the restriction patterns or fingerprints of the clones. The advent of BACs, PACs, BIBACs, and PBCs has facilitated application of the clone fingerprint analysis strategy in the development of BAC-based physical maps of large complex genomes. So far, whole-genome BAC and/or BIBAC-based physical maps have been developed for *Arabidopsis, Drosophila*, rice, human, and mouse.

BAC end sequencing and fingerprint analysis is a combined BAC end sequencing and restriction fingerprinting strategy for genome physical mapping. This strategy has been used in the sequencing projects of *Arabidopsis, Drosophila*, and human to select clones as substrates for sequencing. In this strategy, genome sequencing and physical mapping are performed simultaneously. Both ends of BACs equivalent to about 15 x haploid genomes are first sequenced and entered into computers as a database. Then, seed BACs are randomly selected from the source BAC library, sequenced, and entered into the BAC end database. The sequences of the seed BACs are analyzed against the BAC end sequence database, and the BACs whose ends share common sequences with the seed BACs are selected. Finally, the BACs that are potentially overlapping the seed BACs are fingerprinted and assembled into contigs. According to the fingerprint contigs and BAC end sequences, the minimally overlapping BACs are selected as substrates for continuous sequencing. In this strategy, although no preexisting sequence-ready, BAC-based physical map is required for genome sequencing, a similar amount of effort is needed to develop the physical map as in the genome sequencing progresses. Nevertheless, the global BAC-based physical map would not be available for other applications in genomics research until the genome is completely sequenced. This would be a great loss, considering the utility of the physical map in genomics research.

4.4 Genome Sequencing

Many strategies have been developed and used in large-scale genome sequencing in the past decade; however, shotgun sequencing has become the most dominant strategy. Two alternative approaches, the whole-genome shotgun and the clone-by-clone shotgun, have been developed and used for sequencing large, complex genomes. The whole-genome shotgun approach often involves the following steps: high-quality genomic DNA is purified and randomly sheared; the sheared fragment

ends are enzymatically repaired, size-selected for size-appropriate fragments (e.g. 0.4–2 kbp and 5–20 kbp), and cloned into plasmid-based vectors (e.g. pUC vectors), respectively; template DNA is purified from randomly selected clones, and sequences are generated from both ends of each clone; finally, sequencing data is edited and assembled into contigs with computers. In this approach, the short insert (0.4–2 kbp) clones are used for draft sequence production and contig assembly. The end sequences of the relatively long insert (5–20 kbp) clones are used to link sequence contigs into long-range sequence "scaffolds" and to span long-range repetitive sequences. The "contigs" referred to here are groups of overlapping sequence reads or assemblies without any interruptions, and the "scaffolds" referred to are collections of two or more sequence contigs linked by the relatively large-insert clones. This approach has been used in the sequencing of the human and rice genomes. In the clone-by-clone shotgun approach, HMW genomic DNA is partially digested, size-selected and constructed into large-insert genomic DNA libraries, such as BAC and PAC libraries. A PAC- or BAC-based integrated genetic and physical map of the genome is constructed by using one or more of the physical mapping strategies described above. Minimally overlapping (also referred to as "tiling path") clones that completely cover the entire genome are selected from the physical map and used as substrates for shotgun sequencing, one clone at a time. This approach has been used in the sequencing of the *Arabidopsis* and human genomes. Although both approaches have been used in different large-scale sequencing projects of large, complex genomes, it is obvious that genomic DNA libraries including large-insert DNA libraries are indispensable for both the methods.

4.5 Gene Engineering and Gene Therapy

One of the many applications of DNA libraries is genetic engineering and gene therapy. Genetic engineering and gene therapy have the same basic premise: introduction of DNA clones containing specific new genetic material into an organism's genome. There are many variations of the technology to achieve this goal, depending upon the organism and situation. The basic strategy is to place the new genetic material (e.g. a gene for a new desired function) into the cell, and use the cell's natural machinery to integrate this material into the genome. There are some successful cases for both animal and plant gene engineering.

Animal eggs or embryonal stem (ES) cells can be directly microinjected with gene expression DNA clones or fragments to create a genetically engineered animal. For example, to produce human β-interferon on a large scale, transgenic sheep or cows are used for producing a large amount of casein protein secreted into milk by the mammary gland. The human β-interferon gene has been attached to casein synthesis and secretion signals. High levels of the protein (e.g. 10 g per liter of milk) can be expressed in some animals.

Transgenic plants can be created by the introduction of genes via infection by *Agrobacterium tumefaciens*, a bacterium that can transfer DNA of its Ti plasmid into plant cells, where it integrates into the host plant genome. To date, the main goals of plant engineering are to induce tolerance to herbicides and resistance to insect pests, and to improve crop quality. For example,

a gene from the *Agrobacterium* codes for phosphinothricin-N-acetyltransferase (*PAT*) that inactivates the herbicide Basta. The *PAT* gene is inserted into the toxin gene of the Ti plasmid, transferred into plants via the *Agrobacterium*, and then integrated into the plant genome. When plants are engineered to contain this gene they will have resistance to the glufosinate ammonium herbicides. This allows selective killing of weeds by herbicides.

Gene therapy also involves the introduction of a new gene or the modification of an existing gene (itself or its activity) in cells. Germ-line cell therapy is not allowed in humans; however, somatic cell therapy has been used to treat cystic fibrosis, severe combined immune deficiency (SCID), tumors and other diseases. This kind of gene therapy can be applied to the whole body (*in vivo* therapy) or to the cells removed from a patient (*ex vivo* therapy). In the latter, the engineered cells are returned to the patient.

Recombinant retroviruses or adenoviruses can be used as DNA vectors for gene therapy. Retroviruses can accept up to 7 kbp of introduced DNA and infect only dividing cells. Because of this, they are used in *ex vivo* therapies. Since they integrate into the host genome, their effect is long lasting, but insertional mutagenesis is a potential problem. Retroviruses are used in the treatment of SCID. In contrast, adenoviruses can accommodate larger genes and do not integrate into the host genome. Their effect is transient. The main problem with adenoviruses is the immune response they elicit (used in the treatment of cystic fibrosis and a 1-antitrypsin deficiency). In another approach, recombinant gene clones are encapsulated in liposomes (lipid micels). This method produces no side effects but is less efficient in transferring DNA to target cells. It does not cause an immune reaction. Liposomes can be used *in vivo* and *ex vivo*, and carry any size of DNA fragments. The first gene therapy for a human disease was successfully achieved for SCID by introducing the missing gene of Adenosine Deaminase (ADA) into the peripheral lymphocytes of a 4-year-old girl and returning the modified lymphocytes to her system (1990). As of January 2000, more than 350 gene therapy protocols have been approved in the United States.

5 Concluding Remarks

Technologies for development of DNA libraries are evolving extremely rapidly. Different types of DNA libraries have been developed with different DNA sources, functions, and cloning vectors. The advent of large-insert DNA libraries such as YAC, BAC, PAC, BIBAC, and PBC has revolutionized chromosome walking, whole-genome physical mapping and sequencing of large, complex genomes. Further dramatic improvements in the technology of DNA library construction are to be expected. The applications and potential uses of various DNA clones containing all kinds of genes have made it clear that DNA libraries continue to be indispensable genetic resources and tools for every aspect of molecular research from molecular biology, molecular genetics and genomics to human gene therapy.

Keywords

Enzymatic Photoreactivation
A process in which pyrimidine dimers, produced by ultraviolet (UV) irradiation of DNA, are repaired by their enzyme-catalyzed monomerization.

DNA Photolyase
The enzyme that catalyzes enzymatic photoreactivation of pyrimidine dimers in DNA.

Cyclobutane Pyrimidine Dimers
Covalently joined adjacent pyrimidines in DNA produced by exposure of DNA to ultraviolet radiation.

O6-Methylguanine-DNA Methyltransferase
An enzyme that specifically transfers methyl groups from the methyltransferase O6 position of guanine in DNA to itself.

Base Excision Repair
A DNA excision repair mode, whereby damaged bases are excised as the free bases.

Nucleotide Excision Repair
A DNA excision repair mode whereby damaged bases are excised as nucleotide structures.

Mismatch Repair
A DNA repair mode whereby mispaired bases are excised from DNA.

DNA Damage Tolerance
Any mechanism by which base damage in DNA is effectively bypassed during DNA replication without its removal prior to the bypass.

DNA repair comprises a series of biochemical processes by which alterations of the chemical structure of DNA are eliminated and the DNA is restored to its native state. By strict definition, the term excludes cellular responses by which DNA damage is tolerated but not eliminated from the genome. However, popular usage has incorporated DNA damage tolerance as a mode of DNA repair in a biologically meaningful sense. Hence, for completeness, a particular mode of damage tolerance called *translesion DNA synthesis* (TLS) is included in this discussion.

DNA repair occurs by a variety of distinct biochemical pathways. These differ primarily on the basis of the particular type of damage under consideration. The damage can affect both, the nitrogenous bases and the sugar-phosphate backbone of DNA. The most important form of DNA damage in the latter category is strand breaks. However, this discussion is confined to the repair of damage to the nitrogenous bases in DNA, the informational components of the genetic material. The detailed mechanisms of known DNA repair pathways vary in different organisms. This article considers DNA repair pathways in the yeast, *Saccharomyces cerevisiae*.

1 Yeast as a Eukaryotic Model

Yeasts are eukaryotes, since within each cell the genetic material is contained in a morphologically discrete nucleus. However, yeast cells are not organized into tissues and organs. Thus, they are classified as lower eukaryotes. Nonetheless, the essential parameters of nucleic acid metabolism in yeast cells are very similar to those in higher eukaryotes (including mammals). Thus, yeasts have served as informative models for exploring many aspects of the molecular biology of eukaryotic DNA metabolism.

Yeasts have been shown to be a tractable organism for genetic studies and for recombinant DNA technology. Yeast cells are also easy and inexpensive to grow in the laboratory and have a short life cycle. The latter property provides the further advantage that they multiply rapidly relative to mammalian cells. The two yeasts most widely used in research are the budding yeast *Saccharomyces cerevisiae* and the fission yeast *Schizosaccharomyces pombe*. However, these two yeasts are as evolutionarily distant from one another as each of them is from *Homo sapiens*. This review is confined to a consideration of DNA repair in the yeast *S. cerevisiae*. Thus, the terms yeast and *S. cerevisiae* are used interchangeably here.

2 DNA Repair by the Reversal of Base Damage

Several types of base damage can be repaired by single step biochemical reactions during which specific chemical alterations are directly reversed. The two best-studied examples of this mode of DNA repair in yeast are the enzymatic photoreactivation (EPR) of cyclobutane pyrimidine dimers (CPD) and of [6–4] photoproducts caused by UV radiation, and the repair of O6-methylguanine and O4-methylthymine in DNA caused by exposure to alkylating agents.

2.1 Enzymatic Photoreactivation (EPR)

When living cells are exposed to UV light at wavelengths of ~260 nm (near the absorption maximum for DNA), the absorbed radiation can produce chemical alterations of the bases, resulting in the formation of distinctive photoproducts. The

quantitatively major photoproduct in DNA arises from the covalent joining of adjacent pyrimidines through saturation of the 5,6 double bonds. These altered bases are called *cyclobutane pyrimidine dimers* (CPD) because the covalent linkage between them comprises a cyclobutane ring structure. A second predominant photoproduct is called the *pyrimidine–pyrimidone* (PP) or [6–4] photoproduct ([6–4] PP), in which adjacent pyrimidines are covalently joined through a 6,4 linkage.

Repair enzymes in yeast called *photoreactivating enzymes* or *DNA photolyases* that specifically recognize either CPD or [6–4] PP in DNA catalyze their reversal, generating the native dipyrimidine state (Fig. 1). Both CPD-DNA photolyase and [6–4] PP-DNA photolyase catalyze photochemical reactions that require the presence of light at wavelengths ranging from ~350 to 450 nm. The absorption of light at photoreactivating wavelengths and the specific photochemistry required to monomerize CPD and [6–4] PP is effected by chemical entities called *chromophores* that are noncovalently bound components of all DNA photolyases (Fig. 1). The specific binding of DNA photolyases to substrate sites in DNA does not require the presence of the chromophores or photoreactivating light. Hence, the complete photolyase reaction can be written as follows.

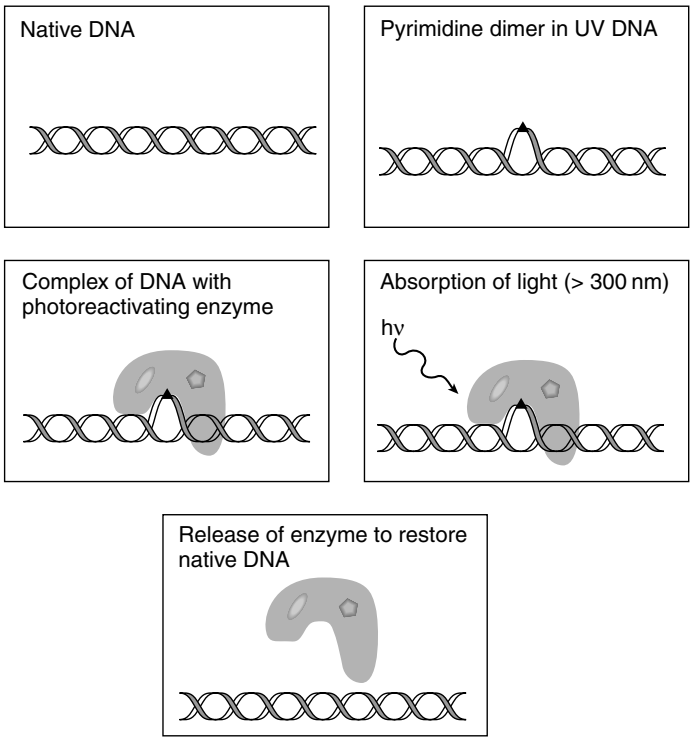

Fig. 1 Schematic representation of the reversal of pyrimidine dimers in DNA by yeast photoreactivating enzyme (pyrimidine dimer-DNA photolyase).

$$E + DNA[Py<>Py] \xrightarrow{\text{Dark reaction}} E - DNA[Py<>Py] \xrightarrow{\text{Light reaction}} E + DNA[PyPy]$$

2.1.1 The Utility of DNA Photolyases

The substrate specificity of DNA photolyases for CPD and [6–4] PP has facilitated the use of this class of DNA repair enzymes as specific probes for the presence of these photoproducts in DNA. Since DNA exposed to UV radiation contains multiple types of photoproducts, it is possible to correlate a particular biological endpoint with the presence of CPD or [6–4] PP, or by showing that the endpoint is mitigated by their removal by enzymatic photoreactivation. This is particularly useful for studies in living cells. The removal of CPD or [6–4] PP from UV-irradiated DNA by incubating DNA in the presence of DNA photolyase *in vitro* also enriches for other types of photoproducts, which may be the primary focus in DNA repair studies. Finally, when used under appropriate conditions, the tight binding affinity of DNA photolyases for CPD and [6–4] PP respectively, in DNA, allows for the detection and quantitation of these lesions.

2.2 Repair of Alkylation Damage by 06-Methylguanine-DNA Methyltransferase

A second ubiquitous example of the repair of specific types of base damage in DNA is that effected by the enzyme O6-methylguanine-DNA methyltransferase. The methylation of oxygen and nitrogen atoms in the nitrogenous bases in DNA is a frequent consequence of the exposure of DNA to reactive alkylating agents, including some that are generated in living cells. Many sites in each of the four bases are sensitive to the covalent addition of small alkyl groups. However, alkylations at O6-G and O4-T are uniquely available for repair by O6-methylguanine-DNA methyltransferase. During the course of this repair reaction, the methyl groups (which can alter the normal base pairing properties of DNA during replication and hence promote mutations) are transferred and covalently attached to a specific cysteine in the enzyme, resulting in the formation of a 5-methylcysteine residue in the polypeptide, thereby inactivating it. Hence, the enzyme is consumed in the reaction in which it participates and acts stoichiometrically rather than catalytically. Such enzymes are called *suicide enzymes*. This novel enzyme also removes ethyl and butyl groups from the O6 position of guanine and the O4 position of thymine in DNA, though less efficiently.

The yeast enzyme is encoded by a gene called *MGT1*. Not unexpectedly, *mgtl* mutants are hypersensitive to the lethal and mutagenic effects of alkylating agents. Such mutants also manifest an increased rate of spontaneous mutagenesis, suggesting that alkylation of O6-G and O4-T occurs naturally in yeast. Natural sources of such spontaneous alkylation damage to DNA have in fact been identified. The amino acid sequence of the yeast enzyme is highly conserved. In all O6-methylguanine-DNA methyltransferase proteins studied, including that from yeast, the same cysteine residue is used as the methyl acceptor species. This cysteine residue is present in the highly conserved penta-amino acid sequence Pro-Cys-His-Arg-Val/Ile. It is not obvious what structural features of alkylated

guanine and thymine provide the exquisite substrate specificity of O6-methylguanine-DNA methyltransferase, although it has been noted that both the O6 position of guanine and the O4 position of thymine occupy the major groove of double-stranded DNA. However, O6-methylguanine-DNA methyltransferase does not catalyze the removal of alkyl groups in other positions on bases, which also project into the major groove. Thus, enzyme specificity is apparently also conferred by oxygen atoms of the nitrogenous bases carrying bound alkyl groups.

3 DNA Repair by the Excision of Base Damage

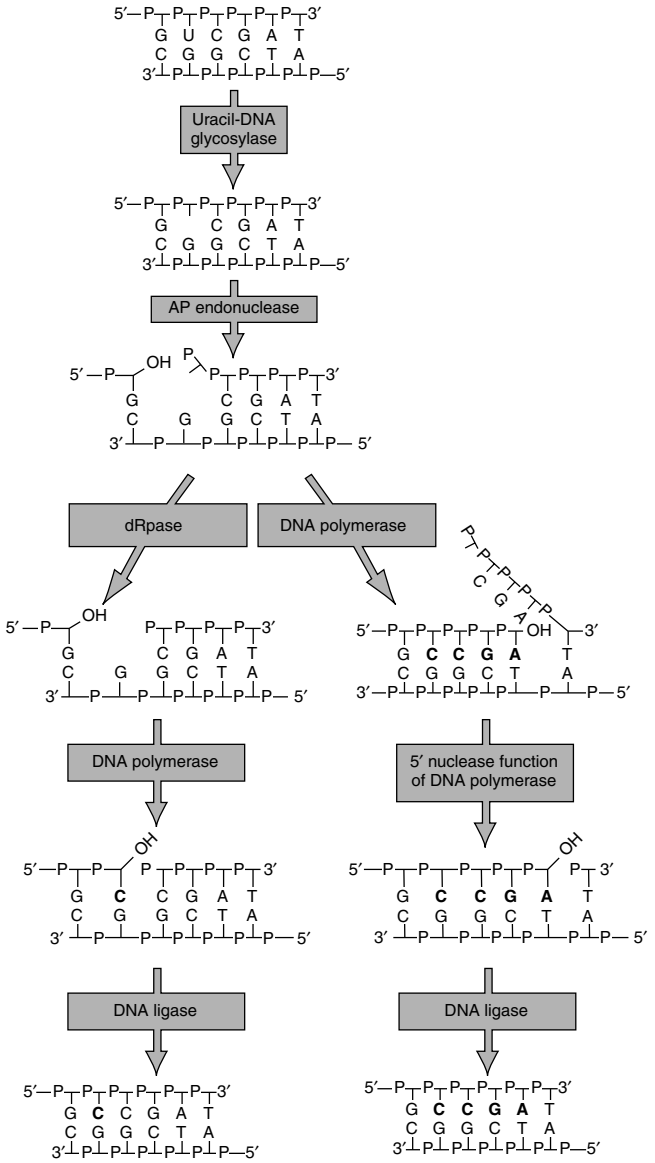
The fundamental paradigm of all excision repair is the physical removal of the damaged, incorrect (with respect to base pairing), or inappropriate (with respect to normal DNA function) bases, and the restoration of normal sequence information by using the opposite intact DNA strand as a template for DNA synthesis. Hence, all excision repair modes require template-directed repair DNA synthesis, that is, double-stranded DNA.

All excision repair modes share in common a requirement for the enzyme-catalyzed removal of damaged bases. In some cases, the damaged (or inappropriate) bases are excised as free bases. This mode of excision repair is called *base excision repair* (BER) (Fig. 2). In other cases, the damaged bases are removed as part of a larger entity, typically an oligonucleotide fragment, which in yeast is ~30 nucleotides long. This mode of repair is called *nucleotide excision repair* (NER) (Fig. 3). There are indications from studies on the yeast *S. pombe* that NER can occur by several biochemically distinct modes. A form of NER that operates specifically on mispaired bases and which is specifically directed to the strand containing the incorrect base is called *mismatch repair* (*MMR*) or *mismatch correction* (Fig. 4).

3.1 Base Excision Repair (BER)

The substrates amenable to BER are determined by the range of specificity exhibited by repair enzymes called *DNA glycosylases* (see below). In general, BER operates on bases that are chemically altered in ways that result in minimal, if any, distortion of the DNA double

Fig. 2 Schematic model of base excision repair (BER) of DNA. The figure shows the presence of a uracil residue in DNA that arose by the deamination of cytosine. This residue is specifically recognized by uracil-DNA glycosylase, which catalyzes its removal, leaving an apurinic (AP) site in the DNA. This site is attacked by an AP endonuclease activity (such as the yeast APN1, human APE or HAP 1 activities), resulting in hydrolysis of the phosphodiester bond 5′ to the AP site. Two possible schemes are shown for further repair of the DNA. On the left, DNA polymerase β inserts a single correct nucleotide and at the same time a dRpase activity excises the 3′ deoxyribose-phosphate moiety generated by the AP endonuclease. DNA ligase (which in human cells is believed to act in concert with XRCC1 protein) ligates the DNA, thereby completing the DNA repair. The scheme shown on the right suggests that, in some cases, a different DNA polymerase may begin synthesis at the site of the nick created by the AP endonuclease, peeling back a 5′ single-stranded region and eventually generating a flap structure. This flap is specifically recognized by an enzyme called Rad27 protein in yeast and DNase IV, MF1 or FEN-1 in mammalian cells. DNA ligation, then, completes the repair as before. (Reproduced with permission from T. Lindahl.)



helix. Many such forms of base damage result from the presence of chemically reactive oxygen species (ROS) in cells. Hence, oxidative base damage is heavily dependent on BER for its repair. Such damage is believed to be an important form of spontaneous mutations.

3.1.1 DNA Glycosylases

During BER, the excision of damaged bases is achieved by the enzyme-catalyzed hydrolysis of the *N*-glycosyl bond that links the base to the rest of the DNA molecule (Fig. 2). Enzymes endowed with this catalytic function are called *DNA*

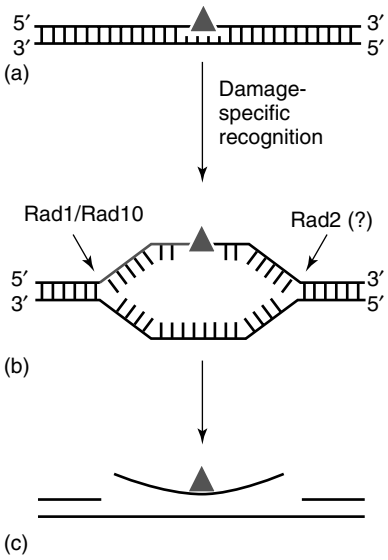


Fig. 3 Cartoon showing the postulated mechanism of bimodal incision of DNA during Global NER in yeast. Following the specific recognition of base damage by the GNER machinery, a ''bubble'' structure is somehow generated. The Rad1/Rad10 enzyme recognizes the junction between double-stranded and single-stranded DNA, and cleaves the 3′ single-stranded DNA. The Rad2 endonuclease similarly recognizes the junction between double-stranded and single-stranded DNA, and cleaves the 5′ single-stranded DNA. The opposite (undamaged) strand must somehow be protected, since *in vivo* incisions are only made on the damaged strand. (Reproduced with permission from E. C. Friedberg, G. C. Walker and W. Siede.)

glycosylases. Yeast and most other living organisms have multiple DNA glycosylases, each of which is more or less specific for different types of base damage. DNA glycosylases are monomeric proteins with no requirement for divalent cations or other cofactors. The first DNA glycosylase discovered is called *uracil-DNA glycosylase* because it exclusively recognizes uracil residues in DNA.

DNA glycosylases are not only endowed with the ability to recognize particular bases but also to only recognize these in the context of deoxyribose linkages. Thus, uracil-DNA glycosylase does not remove uracil from RNA. Some DNA glycosylases have a more relaxed substrate specificity. For example, a DNA glycosylase called 3-methyladenine-DNA glycosylase II not only recognizes 3-methyladenine residues in DNA but also recognizes 7-methylguanine and 3-methylguanine. A 3-methyladenine-DNA glycosylase activity has been identified in yeast cells. The protein is encoded by a gene called *MAG*, which is upregulated when yeast cells are exposed to alkylating agents. Curiously, as is the case with the yeast *PHR1* gene (see above), induction of *MAG* expression also occurs following DNA damage by agents such as UV radiation, which do not result in the formation of alkyl groups in DNA.

3.1.2 AP Endonucleases

The release of free bases catalyzed by DNA glycosylases results in the generation of sites of base loss (apurinic or apyrimidinic sites) in the genome (Fig. 2). The repair of AP sites and hence the completion of the process of BER requires the participation of several other enzymes. Sites of base loss, generated by the action of DNA glycosylases or by spontaneous hydrolysis of N-glycosyl bonds, are attacked by a specific class of endonucleases called apurinic/apyrimidinic (AP) endonucleases. All known AP endonucleases catalyze the hydrolysis of the phosphodiester bond 5′ to the site of base loss generating nicks with 3′-OH and 5′-Phosphate termini (Fig. 2). *In vitro*, some DNA glycosylases (such as the pyrimidine

dimer-DNA glycosylase discussed above) are able to effect cleavage of the 3′-phosphodiester bond at AP sites through a so-called AP lyase activity.

The quantitatively major AP endonuclease activity in yeast is variously designated as yeast AP endonuclease I, yeast DNA diesterase, yeast 3′-phosphoglycoaldehyde

(3′-PGA) diesterase, or yeast AP endonuclease/3′-diesterase. The enzyme has a molecular weight of ~40.5 kDa and is a metalloenzyme. Atomic absorption spectroscopy has revealed the presence of 3.3 Zn^{++} ions per molecule of protein. Nuclease activity is also stimulated by Co^{++} ions. In addition to its AP endonuclease activity, yeast AP endonuclease can excise a variety of 3′ esters in DNA including 3′-phosphoglycoaldehyde, 3′-phosphoryl groups and 3′-α, β unsaturated aldehydes. Like all AP endonucleases, the enzyme hydrolyses DNA 5′ to AP sites, generating 3′-OH and 5′-deoxyribose- phosphate termini.

The structural gene that encodes this AP endonuclease is designated *APN1*. Strains carrying disruptions or deletions of the *APN1* gene are hypersensitive to killing by a variety of oxidative and alkylating agents, which damage DNA. Additionally, such mutants have a spontaneous mutation rate about an order of magnitude greater than that observed in wild-type yeast cells.

3.1.3 Repair Synthesis, Excision and DNA Ligation

The incision of DNA 5′ to sites of base loss provides a normal 3′OH nucleotide terminus for the initiation of repair synthesis of DNA (Fig. 2). The yeast repair synthesis during BER is effected by an enzyme called *DNA polymerase* δ, but a related enzyme, DNA polymerase ε, may also carry out this function. It is not known what specific conditions dictate the preferential utilization of a particular DNA polymerase. The repair synthesis reaction is limited. Only ~2 to 4 nucleotides are inserted. To achieve this, the DNA strand with the 5′-phosphate terminal AP site must be displaced by a limited nick translation. As shown in Fig. 2, displacement of a single strand with a 5′ terminus by repair synthesis would generate a three-stranded flap structure. A yeast enzyme has been identified, which specifically recognizes flap structures with 5′ single-strand tails and removes the single-stranded flap. This protein is encoded by a gene called *RAD27*. The substrate specificity of the Rad27 nuclease has promoted the notion that repair synthesis precedes excision of the AP site during BER as shown in Fig. 2. However, an equally plausible model is that the 5′ terminal AP site is excised first and repair synthesis follows this event.

Figure 2 also shows an alternative repair synthesis/excision reaction for which there is substantial evidence in mammalian cells. In this reaction, a single nucleotide is believed to be inserted by DNA polymerase β. The 5′ terminal AP site is then excised by an enzyme called DNA deoxyribophosphodiesterase (dRpase). Hence, the repair synthesis patch during this putative mode of BER is one-nucleotide long. A dRpase activity has not been identified in yeast. A gene that encodes a polypeptide with the properties of mammalian DNA polymerase β has been cloned from yeast. However, deletion of this gene produces no recognizable phenotype. This does not necessarily mean that the polymerase has no role in DNA repair, since in its absence the alternative longer patch repair synthesis mode may operate exclusively.

3.1.4 DNA Ligation

The final event in all excision repair reactions is the joining of newly inserted nucleotides with 3′-OH termini to the 5′-phosphate terminus of the extant DNA. This joining reaction is catalyzed by an enzyme called *DNA ligase*. A DNA ligase encoded by the yeast *CDC9* gene has been purified and characterized. However, there

are indications that yeast cells contain at least one other DNA ligase activity.

3.2 Nucleotide Excision Repair (NER)

Unlike BER, in which different repair enzymes (DNA glycosylases) recognize different forms of base damage, NER is in general characterized by the recognition of multiple diverse types of base damage by a single repair apparatus. Yeast has been a particularly informative model for deciphering the many genetic and biochemical complexities of NER in eukaryotes. Parallel studies in yeast and mammalian cells have shown that the genes and proteins involved in NER are conserved, and that the detailed biochemistry of this process in these organisms is different from that in bacteria. This structural and functional conservation has allowed for reliable extrapolations from yeast to man, and vice versa, and at the risk of some inaccuracy, we will continue to make such extrapolations in the ensuing discussions. Very recent studies in the yeast *S. pombe* have also provided evidence that NER can occur by more than one biochemical pathway in eukaryotic cells (see later discussion). A fundamental issue yet to be resolved is what determines the broad substrate specificity of the NER apparatus. It appears that two fundamental DNA elements must be present for a DNA lesion to be recognized by NER: the presence of a covalent modification of the DNA, either on a nucleobase or on the phosphodiester backbone, and loss of DNA base pairing. DNA damage recognition is the first step in NER.

3.2.1 NER Mediated by Dual Damage-specific Endonucleases

This excision repair mode is characterized by enzyme-catalyzed incision of the affected DNA strand both 5′ and 3′ to sites of base damage at relatively precise distances from such sites, generating oligonucleotide fragments ~30 nucleotides long, which are subsequently excised (Fig. 3). During NER, the 5′ incisions are located ~22 nucleotides from the sites of damage while the 3′ incisions are located just five nucleotides from these sites (Fig. 3). This precise spacing of nicks is believed to result from the formation of a discrete "repair bubble" ~30 nucleotides long by unwinding of the DNA duplex around the site of base damage (Fig. 3). This repair bubble is generated by the action of two DNA helicases, Rad3, and Rad25 (Ssl2) that unwind DNA in opposite directions. The two DNA helicases are part of a larger protein complex called TFIIH that participates in both NER and RNA polymerase II transcription (see later discussion).

Other proteins specifically recognize and cleave double-strand/single-strand junctions in DNA with polarities that are specified by the directionality of the single-stranded DNA. Hence, the 5′ endonuclease for NER in yeast, consisting of a heterodimer of the products of the *RAD1* and *RAD1O* genes, cleaves the 3′ single-stranded DNA at double-strand/single-strand junctions *in vitro* (Fig. 3). In contrast, the 3′ endonuclease, consisting of the monomeric product of the yeast *RAD2* gene, specifically cleaves the 5′ single-stranded DNA at double-strand/single-strand junctions (Fig. 3). So the substrate specificity for incision of damaged DNA during NER is determined by the presence of duplex-/single-stranded DNA junctions generated by the TFIIH helicases rather than by the damaged bases themselves.

Besides the Rad1, Rad1O, Rad2, Rad3, and Ss12 proteins, the nucleotide excision machinery in yeast includes at

least six other proteins designated Rad4, Radl4, Ssl1, Tfb1, Tfb2, Tfb3, and Tfb4 (Fig. 5). Rad14 protein binds preferentially to damaged DNA *in vitro*. The Rad4 and Rad23 proteins may be involved in the recognition of base damage as well, and the Rad7 and Radl6 genes are believed to be required for the post-incision excision of oligonucleotide fragments. All of the proteins required for NER in yeast are believed to be assembled into a large multiprotein complex called the *nucleotide excision repairosome* (Fig. 5).

3.2.2 Proteins for NER are Required for Transcription by RNA Polymerase II

As mentioned above, Rad3, Ss12, Ssl1, Tfb1, Tfb2, Tfb3, and Tfb4 proteins are components of a protein complex called TFIIH, which in concert with several other transcription factors is required for the initiation of basal transcription by RNA polymerase II. It has been demonstrated that Rad3, Ss12, Ssl1, and Tfbl are indispensable for NER *in vitro* and it is likely that the same is true of the Tfb2 and Tfb3 proteins. Hence, all six of these proteins are probably bifunctional, with obligatory roles in Global NER and in RNA polymerase II transcription.

3.2.3 NER Mediated by a Single Damage-specific Endonuclease Activity

Recent studies in the yeast *S. pombe* have identified a novel endonuclease that recognizes CPD and [6–4] photoproducts, as well as various bulky chemicals in DNA. The enzyme nicks DNA uniquely 5′ immediately adjacent to sites of damage. The events that follow the 5′ incision event are not yet known. It is likely that the physical excision of the base damage (presumably as part of an oligonucleotide fragment) is effected by events associated

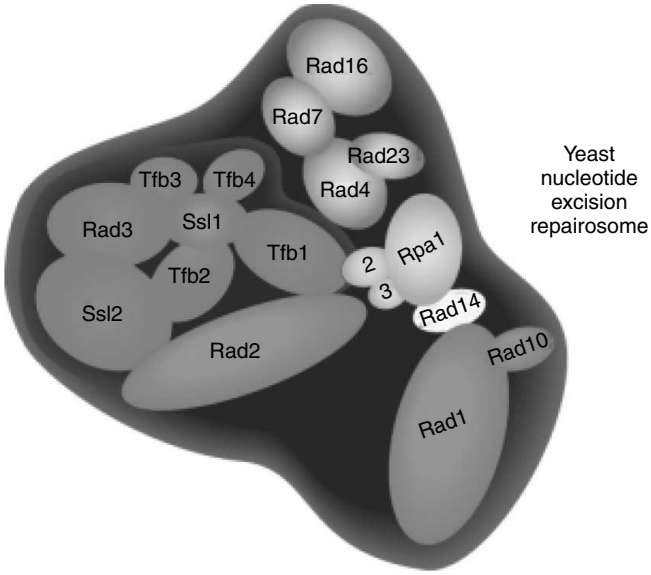

Fig. 5 A cartoon showing all the known protein subunits of the fully assembled yeast nucleotide excision repairosome. The subcomplex comprising Rad3, Ssl2, Tfb1, Tfb2, Tfb3, and Tfb4 proteins is called TFIIH.

with repair synthesis and nick translation, without a requirement for a second endonuclease.

3.3 Mismatch Repair

Mismatch repair refers to biochemical events that result in the excision of mismatched bases from DNA. The repair of mismatches can occur by either a BER mode or a NER mode, that is, the mismatched bases can be excised as free bases or as nucleotides. The BER mode of MMR is limited to certain mismatches and has not been identified in yeast. In contrast, the NER mode of MMR is ubiquitous and appears to be mechanistically conserved from prokaryotes to humans. During semiconservative DNA synthesis in *E. coli*, newly replicated DNA strands are methylated at GATC tetranucleotide sequences. The kinetics of this process results in a period of transient undermethylation of these strands. The MMR system exploits this chemical difference to provide strand specificity for the excision of mispaired bases. In *E. coli*, the presence of both mismatched bases and undermethylated (at GATC sequences) DNA results in the binding of proteins encoded by the *mutS* and *mutL* genes. The formation of a bound MutS/MutL complex activates a latent endonuclease in a protein encoded by the *mutH* gene, resulting in the incision of the newly replicated DNA strand at an unmethylated GATC sequence. This nick can occur either 5′ or 3′ to a mismatch and initiates degradation of the DNA between the nick and the mismatch, resulting in excision of the latter. The excision reaction, which is dependent on the MutS and MutL proteins, a DNA helicase and an exonuclease, results in the excision of a tract of DNA that extends from the site of the mismatch to the site of incision at the nonmethylated GATC sequence.

Homologous systems for MMR have been identified in yeast and in higher eukaryotes. Yeast DNA is not methylated, hence the molecular basis for the strand specificity during MMR in this organism is unknown. Six yeast genes have been shown to be homologous to the *E. coli MutS* gene, designated *MSH1 – MSH6* (for Mut S Homolog) (Fig. 4). The MSH4 and MSH5 proteins are not believed to function in MMR, but rather in meiotic recombination events. MSH1 protein is targeted to mitochondria. The MSH2, MSH3, and MSH6 proteins bind mismatched and looped-out DNA bases as heterodimeric protein complexes. MSH2 and MSH6 form a complex known as MutSα, while MSH3 and MSH6 form MutSβ (Fig. 4). Homologs of *E. coli* MutL protein include MLH1, MLH2, MLH3, and PMS1. Several of these factors also form heterodimeric protein complexes with each other that interact with the MutSα and MutSβ complex *in vitro*. The MLH1-PMS1 complex is known as MutLα, which interacts with both MutSα and MutSβ. MLH1 and MLH3 form the complex MutLβ, which interacts with MutSβ.

MutSα binds most readily to single base mismatches while MutSβ prefers longer looped-out regions of DNA. MutLα increases the affinity of either MutSα or MutSβ for mismatched or looped DNA. Additionally, ATP binding to MutLα induces a conformational change. In *E. coli*, MutL increases the translocation of MutS in traversing from the mismatch site to the nearest site of hemimethylation that establishes strand specificity, the nonmethylated strand being the newly synthesized DNA and hence the strand requiring correction. As already mentioned, the same mechanism cannot hold for yeast and it has

been postulated that a MutLα conformational change may recruit the necessary factors for subsequent events of MMR such as strand discrimination.

The other required factors for MMR have not been determined, but likely include EXO1, which interacts with MSH2, MSH3, and MLH1. EXO1 is a DNA nuclease but bears homology to the XPG/FEN1 family rather than *E. coli* MutH. The EXO1 relationship to MMR has also been suggested genetically through epistasis analysis. Hence, EXO1 may function as the exonuclease required for removal of mismatched DNA or loops. Additionally, Proliferating Cell Nuclear Antigen (PCNA) has been shown to interact both with MutSα and MutSβ through MSH6 and MSH3, respectively. PCNA is also capable of disrupting MutSα-MutLβ-mismatched DNA complexes. Interaction with PCNA suggests that yeast MMR is influenced by the DNA replication machinery, which perhaps affords a basis for strand discrimination.

4 DNA Damage Tolerance by Translesion DNA Synthesis (TLS)

Various types of base damage can impede or completely arrest normal high-fidelity DNA replication, thereby compromising the ability of cells to traverse the cell cycle during cell division. To avoid cell death, cells have evolved multiple mechanisms to bypass the arrested DNA replication machinery (Fig. 6). One of these utilizes several specialized DNA polymerases that have the ability to bypass template lesions that block DNA replication by the process of translesion DNA synthesis. Higher eukaryotes are endowed with at least nine such polymerases; the genome of *S. cerevisiae* reveals open reading frames for just three of these called Rev 1, DNA polymerase ζ (polζ) and DNA polymerase η (polη). Rev1 may not be a true translesion polymerase since its catalytic activity is almost exclusively confined to the incorporation of cytidine into DNA. Hence, Rev1 is also referred to as dCMP transferase. Polη and Polζ are typical translesion polymerases. Like all such enzymes, these two polymerases are endowed with a structure that facilitates their ability to replicate past various types of DNA lesions. This relaxed fidelity results in markedly reduced accuracy for nucleotide incorporation when copying either damaged or undamaged DNA. Hence, these polymerases are highly error prone and can generate mutations. Their potential for mutagenic DNA synthesis presumably requires that they do not normally access the genome when not required for translesion DNA synthesis.

Polη is highly conserved in higher eukaryotes and in human cells has been identified as the product of the *XP V* gene, which when inactivated, results in the disease xeroderma pigmentosum (XP). XP is characterized by extreme sensitivity to sunlight with a markedly increased predisposition to cancer in exposed areas of the skin. Like the human enzyme, yeast polη is able to bypass thymine–thymine dimers and possibly other CPDs. In doing so, it incorporates adenine opposite the dimerized thymines with the same relative accuracy as it incorporates adenine opposite native adjacent thymine pairs. It has been similarly demonstrated to bypass other types of base damage with relative accuracy. Hence, it would appear that polη has evolved to bypass many types of base damage with relative accuracy in *S. cerevisiae*. The biological role of polζ is not known. *In vitro*, this enzyme, like polζ,

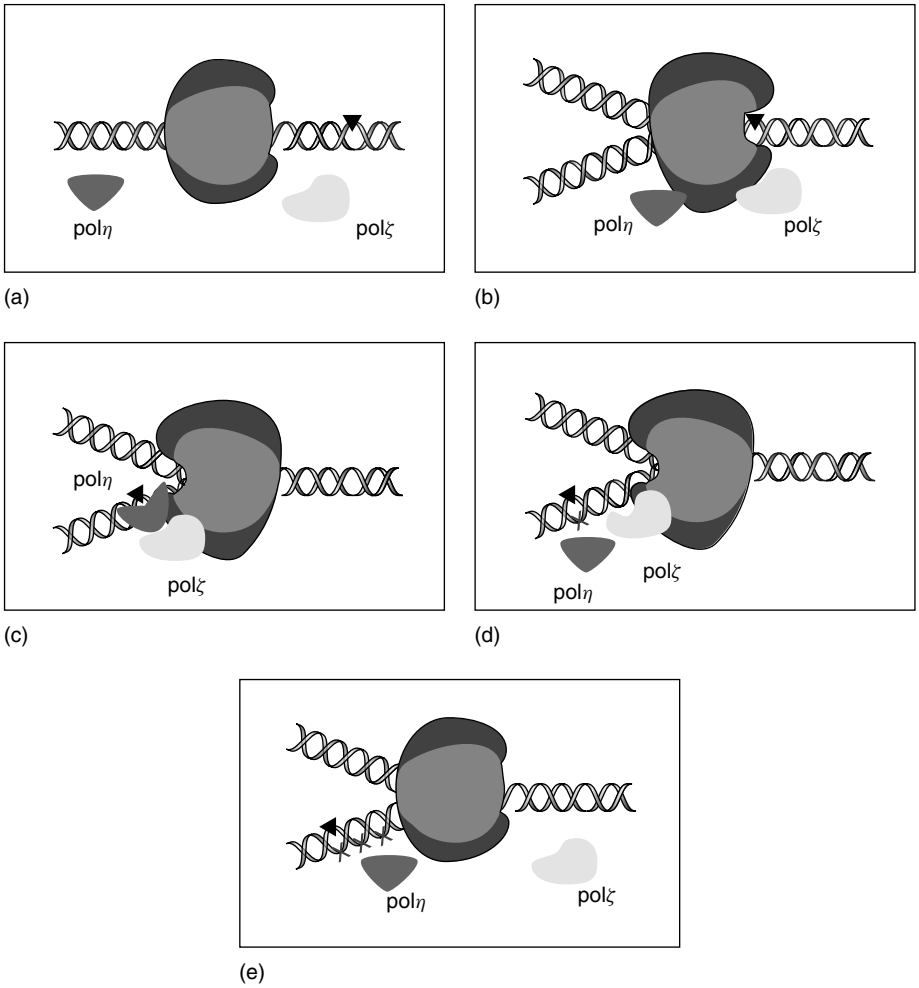

Fig. 6 Diagrammatic representation of TLS by two specialized polymerases in yeast, Polη and Polζ. These polymerases overcome blocks in replication caused by a DNA lesion (a) The DNA replicative machinery stalls immediately behind a site of base damage (triangle). (b) The two specialized polymerases (η and ζ) bind to the arrested replication complex. (c) This interaction promotes a conformational change in the arrested replication machinery placing Polη in direct proximity to the site of base damage, allowing DNA synthesis across the lesion. (d) Polη dissociates and allows Polζ to complete the process of replicative bypass by incorporating several more nucleotides. Once the lesion has been completely bypassed, the polζ dissociates and the replicative machinery assumes DNA replication. Changes to the DNA sequence are incorporated as a result of this process, known as *translesion synthesis*.

can bypass various types of base damage. It remains to be determined whether polζ merely serves as a backup TLS polymerase function in yeast, or has some other function. Studies on TLS polymerases in general suggest that polζ may function primarily, if not exclusively, to extend DNA synthesis beyond sites of TLS by

enzymes like polη. Thus, TLS is considered to be a two-step process involving the incorporation of one or two nucleotides opposite sites of base damage by one TLS enzyme, followed by extension of the primer terminus for a limited number of nucleotides. These two DNA synthesis events may well be coupled.

The precise mechanism whereby the replication machinery switches places with one or more TLS polymerase at the primer terminus of a site of arrested DNA replication is unknown. Nor is it known how a particular TLS enzyme or enzyme pair is selected for the bypass of a particular lesion. The mutations generated by TLS are not necessarily always deleterious. Genomic infidelity is a required backdrop for Darwinian evolution.

Keywords

Origin (ori)
A unique site on the chromosome from which DNA replication starts in either one or both directions.

Replication Fork
A moving front of DNA replication at which a double-stranded DNA helix is separated into two newly replicated helices.

DNA Polymerase
An enzyme that catalyzes the formation of DNA chain by adding deoxyribonucleotides to the 3′-hydroxyl end of a preexisting DNA strand.

Promoter
A region on a DNA molecule in which an RNA polymerase binds and initiates transcription.

Transcription Factor
A class of regulatory protein that binds to a promoter or to a nearby sequence of DNA to facilitate or prevent initiation of transcription.

RNA Polymerase
An enzyme that transcribes an RNA molecule from one strand (template strand) of a DNA molecule.

Genetic information of organisms is kept in DNA in the form of an array of nucleotide sequences, and the cell must precisely replicate its chromosomal DNA. The self-complementary nature of the double-stranded DNA molecule is the basis for accurate replication, and organisms are equipped with DNA polymerase enzyme, which adds deoxyribonucleotides to preexisting DNA chains in the $5' \rightarrow 3'$ direction, along the template strand of DNA. One strand (the leading strand) is synthesized continuously while the other (the lagging strand) is synthesized discontinuously and is then sealed.

To extract information from DNA, a limited region of the DNA, which constitutes the gene or the gene cluster (operon), is transcribed into RNA. This process is catalyzed by RNA polymerase. As is the case with DNA polymerase, this enzyme is composed of multiple subunits and catalyzes the addition of ribonucleotides to the growing RNA chain in the $5' \rightarrow 3'$ direction, along the template DNA. Both the startpoint and the frequency of transcription are determined by the promoter, a specific sequence of DNA to which RNA polymerase and transcription regulatory proteins can bind.

1 DNA Replication

Precise transmission of chromosomal DNA from generation to generation is crucial to cell propagation. This can only be achieved when chromosomal DNA is accurately replicated, providing two copies of the entire genome for faithful distribution into each daughter cell. To this end, the cell has special mechanisms to maintain the high fidelity of DNA replication, to segregate the replicated DNA, and to coordinate DNA replication and cell division tightly within the cell cycle.

Interest and research in DNA replication have been fueled by increasing concerns with mutagenesis, evolution, carcinogenesis, and cancer therapy. Spontaneous mutations, apparently a major force in evolution, arise largely from errors during DNA replication. Cancer cells, having multiple mutations in genes controlling the cell cycle, escape the tight regulation of cell cycle and start their chromosomal DNA replication abnormally. This uncoupling of cell division and DNA synthesis may frequently induce chromosome disorders and additional mutations, thus accelerating the malignancy. Most anticancer treatments involve inhibition of DNA replication in cancer cells.

Many basic concepts and techniques in modern biotechnology are derived from research on DNA replication. The development of cloning vectors has depended on the knowledge of the replication mechanisms of bacterial plasmids and phages. Genetic engineering, DNA sequencing, and the polymerase chain reaction (PCR) utilize replicative enzymes, such as DNA polymerase and DNA ligase.

1.1 Structural Aspects of DNA Replication

The double-stranded nature of DNA provides the basis for its semiconservative replication. The two strands of the parental duplex contain complementary sequence information. DNA synthesis by a polymerase also makes use of this complementarity in generating the daughter duplex. A faithful copy can be made by complementary base pairing between the free nucleotide substrate and the parental DNA strand template. Thus, the daughter duplex consists of one parental strand and one new strand. Complementary base pairing also allows for the correction of replication errors by several repair mechanisms.

1.1.1 Replicon: Unit of Replication

DNA replication does not start at random locations but at particular sites, called the *origins of DNA replication*. A DNA whose replication starts from an origin and proceeds bidirectionally or unidirectionally to terminus site(s) is called a *replicon*, a unit of DNA replication. In bacterial cells, the circular chromosome contains a unique origin and DNA replication proceeds bidirectionally from the origin to the terminus (Fig. 1(a)). Therefore, the whole bacterial genome (4700 kb for *Escherichia coli*) is a single replicon. This genome structure is also common to most bacterial plasmids and some phages, although some of them are replicated unidirectionally.

On the other hand, eukaryotic cells contain multiple replication origins on each chromosome (Fig. 1(b)). In order for the eukaryotic cell to replicate its huge genome (2900 Mb per human haploid genome) in a relatively short period (about 7 h for the S-phase in a cultured animal cell), many replicons function simultaneously. Each replicon is 40 to 100 kb in size

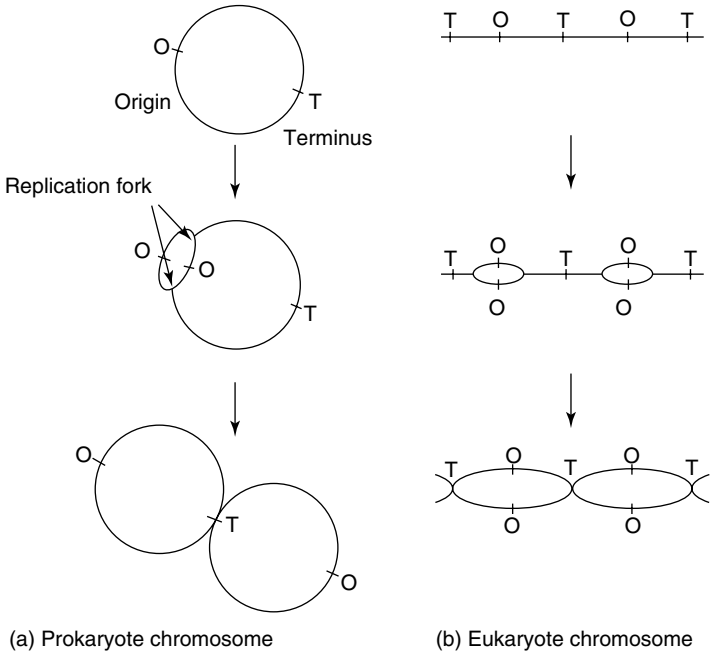

Fig. 1 Unit of DNA replication in prokaryotic and eukaryotic cells. Symbols: O = replication origin, T = replication terminus.

and the number of replicons utilized depends on the growth state of the cell: more rapidly growing cells use more replicons. There are some exceptional cases, such as the early embryonic divisions of *Drosophila* embryos, where the duration of the S-phase is compressed by the simultaneous functioning of a large number of replicons.

1.1.2 **Replication Fork**

In each replicon, replication is continuous from the origin to the terminus and is accompanied by the movement of the replicating point, called the *replication fork*. Both parental DNA strands are concurrently replicated at the fork. Since DNA polymerase can extend a DNA chain only in the 5′ → 3′ direction, replication at a fork is semi-discontinuous (Fig. 2): DNA synthesis is continuous on one strand (leading strand) and discontinuous on the other (lagging strand). Short pieces of DNA, called *Okazaki fragments*, are repeatedly synthesized on the lagging-strand template, with these Okazaki fragments being a few thousand nucleotides in bacterial cells and a few hundred nucleotides in eukaryotic cells.

The velocity of fork movement has been estimated from the size of a replicon and the length of its replication period. In *E. coli*, the replication fork proceeds at 1000 bp/s and one Okazaki fragment is synthesized every 1 to 2 s. In eukaryotic cells, the rate of fork movement is slow, 10 to 100 bp/s. The distinction between prokaryotic and eukaryotic replication may be due to a difference in the replication machinery or in the structure of the chromosome.

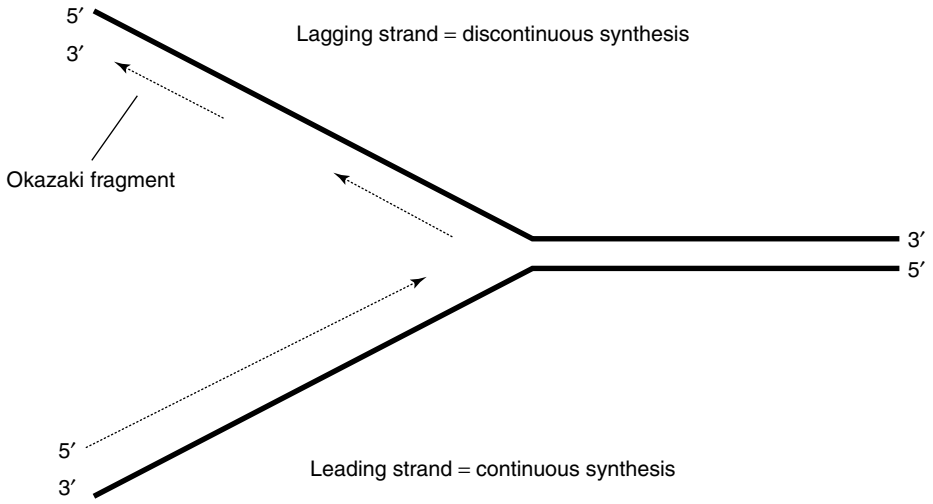

Fig. 2 Semi-discontinuous DNA synthesis at the replication fork.

1.2 Biochemistry of DNA Replication

DNA replication is a complex process involving numerous enzymes at the replication fork. In *E. coli*, more than 20 different proteins participate in DNA replication. These were identified by screening of mutants defective in DNA replication and by purifying enzymes required for *in vitro* DNA synthesis. On the basis of their biochemical roles in different stages of chromosomal DNA replication, these proteins are classified into several categories: (1) proteins involved in the initiation of replication: DnaA, HU, DNA gyrase, single-stranded DNA binding protein (SSB), DnaB, DnaC, RNaseH1, and RNA polymerase; (2) proteins required for chain elongation and connecting Okazaki fragments: DnaG (primase), DNA polymerase III (Pol III) holoenzyme, SSB, DNA polymerase I (Pol I), RNaseH1, and DNA ligase; (3) a swivel to relieve torsional stress in advance of the replication fork: DNA gyrase; (4) proteins for the termination of replication and segregation of daughter molecules: terminus binding protein (Tus), DNA gyrase, and DNA topoisomerase IV; (5) primosome proteins required for reformation and restart of replication fork when it accidentally collapses: PriA, PriB, PriC, DnaT, DnaB, DnaC, and DnaG. Among these proteins, the DnaB helicase, primase (DnaG), and Pol III holoenzyme are the basic components acting at the replication fork, forming a multiprotein complex called a *replisome* (Fig. 3).

Replication of many bacterial plasmids and small phages requires most of the host-encoded replication proteins, although the initiation step of these extra chromosomal replicons differs from that at the host origin. Large phages such as T4 and T7 encode their own replication proteins, whose activities resemble those of the *E. coli* replication proteins. In eukaryotic cells, chain elongation, termination, and segregation appear to be carried out by activities very similar to the *E. coli* replication proteins. Proteins involved in the

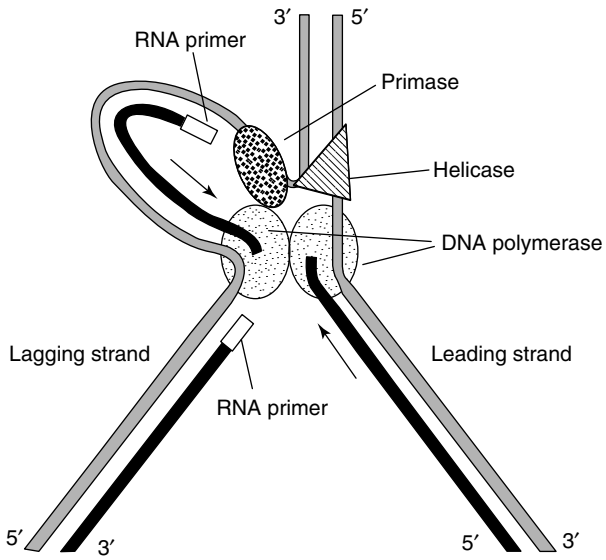

Fig. 3 Hypothetical structure of replication machinery. Primase, DNA helicase, and twin DNA polymerases form a "replisome."

initiation of chromosomal replication in eukaryotic cells have also been identified.

1.2.1 DNA Polymerase

DNA polymerase plays a primary role in replication, catalyzing synthesis of a DNA chain complementary to the template DNA strand as follows:

$$(\mathrm{dNMP})_n + \mathrm{dNTP} \longrightarrow (\mathrm{dNMP})_{n+1} + \mathrm{PP_i}$$

The reaction absolutely requires three components: (1) deoxynucleosidetriphosphate (dNTP) as a substrate; (2) single-stranded DNA as a template; and (3) a short RNA or DNA as a primer. The primer must be annealed to the template by base pairing and its 3′-terminus must possess a free 3′-OH group. Chain growth is exclusively 5′ → 3′ since the polymerization mechanism is a nucleophilic attack by the 3′-OH group of the primer on the α-phosphate of the incoming dNTP. The products are a new primer, longer by one nucleotide, and an inorganic pyrophosphate. 2′,3′-dideoxy NTP can be incorporated by some DNA polymerases, but blocks chain elongation because it lacks a free 3′-OH group. This chain termination property is utilized in some DNA sequencing methods.

Both prokaryotic and eukaryotic cells possess multiple numbers of distinct DNA polymerases (Table 1), which differ in their structures as well as in their biochemical and biological functions. A 3′ → 5′ exonuclease activity is associated with all replicative DNA polymerases except the eukaryotic Pol α. The fidelity of DNA synthesis is increased by the 3′ → 5′ exonuclease activity, which allows for removal of nucleotides incorrectly inserted by the polymerase.

In *E. coli*, Pol III holoenzyme is the major replicative polymerase for both leading-

Tab. 1 DNA polymerases found in prokaryote and eukaryote.

Organism	*DNA polymerase*	*Processivity*	*Editing exonuclease*	*Function*	*Unique features*
E. coli	Pol I	Low	Yes	Repair	$5' \rightarrow 3'$ exonuclease associated
	Pol II	Medium	Yes	TLS	Structural homology to eukaryotic Pol α
	Pol III	High	Yes	Replication	Asymmetric dimer with twin active site
	Pol IV	Low	No	TLS	Capable of induction of frameshifts
	Pol V	Low	No	TLS	Activated by RecA protein
Mammal	Pol α	Medium	No	Replication	Primase associated
	Pol β	Low	No	Repair	Small single-polypeptide
	Pol γ	High	Yes	Mitochondrial replication	Preference to ribohomopolymer template
	Pol δ	High	Yes	Replication, repair	PCNA-dependent processivity
	Pol ε	High	Yes	Replication, repair	PCNA-independent processivity
	Pol ζ	Low	No	TLS	Mismatch extender polymerase
	Pol η	Low	No	TLS	Error-free bypass DNA synthesis
	Pol ι			TLS	Most error-prone polymerase
	Pol κ	Medium	No	TLS	Related to *E. coli* Pol IV
	Pol λ	Low	No	Repair in meiosis?	Homologous to Pol β
	Pol μ	Low	No	Somatic hyper mutation?	Expressed preferentially in lymphoid

Note: TLS: translesion DNA synthesis.

and lagging-strand synthesis. Pol I participates in lagging-strand synthesis by eliminating primer RNAs and also has a role in repair synthesis. The other three polymerases, Pol II, Pol IV, and Pol V, are involved in translesion DNA synthesis and are induced when the chromosome DNA is damaged. The Pol III holoenzyme is a huge multiprotein complex that consists of 10 distinct polypeptides. This enzyme extends the DNA chain with a high processivity (>500 kb of DNA can be

continuously synthesized without dissociation of polymerase from the template) and a high catalytic efficiency (the velocity of chain elongation is 1000 nucleotides second at 37 °C). The catalytic core, composed of α-, ε-, θ-subunits, contains the polymerase activity and a $3' \rightarrow 5'$ exonuclease for proofreading. τ-subunit connects two of the catalytic core subassemblies. The remaining six auxiliary subunits enhance the processivity of the core by clamping it onto the template. They also promote the repeated association of the polymerase necessary for discontinuous synthesis of the lagging strand. Among the auxiliary subunits, a dimer of β-subunit shows a ring-shaped structure and acts as a sliding clamp. Loading of the β-clamp onto the DNA is facilitated by a five-subunits subassembly called *γ-complex*. Structural analysis of the Pol III holoenzyme and studies on a reconstituted replication fork suggest that the holoenzyme is a functionally asymmetric dimer with twin polymerase active sites: one half of the dimer has high processivity and might be a polymerase for continuous synthesis of the leading strand; the other half has recycling capacity needed for the lagging-strand synthesis. Thus, a single molecule of Pol III holoenzyme acts at the replication fork catalyzing concurrently both leading and lagging-strand synthesis.

In eukaryote cells, nuclear DNA replication requires three polymerases, Pol α, Pol δ, and Pol ε. Pol γ is a sole polymerase participating in mitochondrial DNA replication. Pol β, a small single polypeptide, functions in base excision repair. There are many other polymerases that were recently identified. Some of them are involved in translesion DNA synthesis, but biological roles of the remaining polymerases are unknown. Among the replicative polymerases, Pol α is unique in possessing a primase activity, the only such activity so far identified in eukaryotic cells, suggesting that Pol α may play a role in the priming of DNA synthesis. However, DNA synthesis by Pol α, lacking the $3' \rightarrow 5'$ exonuclease activity, is inaccurate and shows a low processivity. These enzymatic characteristics make Pol α a poor candidate for the major replicative polymerase. On the other hand, Pol δ and Pol ε both possess a $3' \rightarrow 5'$ exonuclease activity and are able to carry out highly processive DNA synthesis with the aid of a sliding clamp (PCNA) and a clamp loader (RF-C). Therefore, these polymerases are better suited for chromosome replication. Yeast mutant strains defective in the $3' \rightarrow 5'$ exonuclease activity of either Pol δ or Pol ε increase spontaneous mutation rate, suggesting that both polymerases are responsible for chain elongation during chromosome replication. However, the division of labor between the polymerases remains ambiguous.

1.2.2 DNA Helicase and Primase

DNA polymerase cannot replicate a duplex DNA without assistance. This enzyme requires single-stranded DNA as a template and cannot synthesize a chain without an RNA or DNA primer annealed to the template. Two other enzymes enable polymerase to work on a duplex DNA. One is a DNA helicase, which opens up the duplex at the replication fork to provide a single-stranded template. The other is a primase, which synthesizes a short RNA to prime DNA chain elongation.

Several DNA helicases have been identified from *E. coli* and its phages, including DnaB, T7 gp4, and T4 gp41. Biochemical characterization of these activities *in vitro* DNA replication systems suggests that the primary replicative helicase binds

to and moves on the lagging-strand template in the 5′ → 3′ direction unwinding the duplex as it goes. This helicase action requires ATP hydrolysis. In addition, genetic studies indicate that these helicases are essential for DNA replication and growth of the cell or its phages, respectively. Another common property of the replicative helicases is an intimate association with a primase. The T7 gp4 has both primase and helicase activity within the same polypeptide. T4 gp41 greatly enhances the primase activity of T4 gp61. A similar functional interaction has been observed between DnaB protein and *E. coli* primase (DnaG protein).

Although several DNA helicase activities have been found in eukaryotic cells, the replicative helicase has not been clearly identified. Large T-antigen encoded by the SV40 virus is required for the replication of SV40 DNA and has a 3′ → 5′ helicase activity. Moreover, human DNA Pol α, which contains a primase subunit, has a specific affinity to the large T-antigen helicase. Most recently, MCM2-7 proteins that form a ring-shaped complex around DNA and that are required for chain elongation during chromosomal replication were suggested to be a replicative helicase.

Primases can start a new chain when copying a duplex DNA, but, like DNA polymerases, require a single-stranded DNA as the template. Primases can utilize dNTPs in place of rNTPs, although they absolutely require an rNTP (ATP in most cases) to initiate the primer. Under physiological concentrations, rNTPs are preferentially used during primer synthesis. In prokaryotes, primer synthesis is initiated at preferred sequences on the template: 3′-GTC for *E. coli* primase (DnaG), 3′-CTG(G/T) for T7 phage primase (gp4), and 3′-TTG for T4 phage primase (gp61). The sequence preference of the initiation of primer synthesis by eukaryotic primases is uncertain. All primases found in various organisms extend the primer chain in the 5′ → 3′ direction to a particular length: 10 to 12 nucleotides by DnaG protein, 4 nucleotides by T7 gp4, 5 nucleotides by T4 gp61, and 8 to 12 nucleotides by eukaryotic primases.

A functional interaction between primase and replicative helicase has been extensively studied using *E. coli* replication proteins. On most templates, DnaG exhibits a very feeble priming activity, which can be greatly enhanced if DnaB first binds that DNA. This stimulation of primase activity is further increased when the DnaB helicase is activated to its processive form at the replication fork. The activation of DnaB protein is a key step in the initiation of DNA replication and is catalyzed in several ways (see Sect.1.3.2).

1.2.3 Other Replication Proteins

In addition to the components of the replisome, several auxiliary proteins are needed for DNA replication. Single-stranded DNA binding protein (SSB) protects the exposed template and stabilizes the structure of the replication fork. *E. coli* mutants defective in SSB are inviable; DNA synthesis in these conditional mutants stops quickly under nonpermissive conditions. *E. coli* contains about 300 molecules of SSB per cell, at a level sufficient to cover about 1400 nucleotides of the lagging-strand template at each replication fork. Eukaryotic counterpart to the *E. coli* SSB has been identified in the *in vitro* replication system. This protein, RF-A, consists of three distinct subunits, binds tightly to ssDNA, and is required for the helicase action of the virus-encoded T-antigen at the SV40 origin.

Enzymes to remove the primer RNA and fill the gap, such as RNaseH1 and

DNA polymerase I of *E. coli*, are essential for the sealing of Okazaki fragments by DNA ligase. Mutants defective in either DNA polymerase I or DNA ligase show a massive accumulation of short Okazaki fragments under restrictive conditions. In eukaryote, a $5' \rightarrow 3'$ exonuclease called *FEN1* removes the primer RNA.

DNA topoisomerases function as swivels, to relieve torsional stress produced ahead of the replication fork. From the analysis of mutants, it appears that DNA gyrase (a type II topoisomerase from *E. coli*) acts as the swivel in prokaryotic cells. In eukaryotes, either type I or type II topoisomerases can provide the swivel action needed. Another important role of topoisomerases in replication is the decatenation of daughter molecules. This function is provided by type II topoisomerases in both prokaryotic and eukaryotic cells and allows the separation of the daughter molecules prior to segregation.

1.3 Regulation of DNA Replication

Initiation of DNA replication is a major determinant of the cell cycle, and thus is tightly regulated in all organisms. Although signals that turn on DNA replication in eukaryotic and prokaryotic cells are different, how these signals are transduced to the initiation machinery is one of the most important issues in cell biology. The mechanisms of initiation have been detailed using systems that initiate and replicate a minichromosome *in vitro*. These various mini-chromosomes contain replication origins from bacterial chromosomes (*E. coli oriC*), bacteriophages (λ *ori*, P1 phage *ori*), and plasmids (ColE1 *ori*, F plasmid *oriS*). In contrast to the prokaryotic origins, the sequences required for an origin of replication vary significantly between different eukaryotic organisms. Chromosomal origins have been isolated from yeast as well as from several eukaryotic viruses. However, attempts to identify such autonomously replicating segments from animal or plant chromosomes have been unsuccessful. Instead, a more direct approach, using electron microscope and two-dimensional gel electrophoresis techniques, has been taken to identify replication origins in the higher eukaryotes. Although it has been difficult to develop *in vitro* systems for eukaryotic DNA replication, genetic studies with yeast mutants that affect initiation processes of chromosomal replication have successfully revealed the initiation mechanisms of eukaryotic DNA replication.

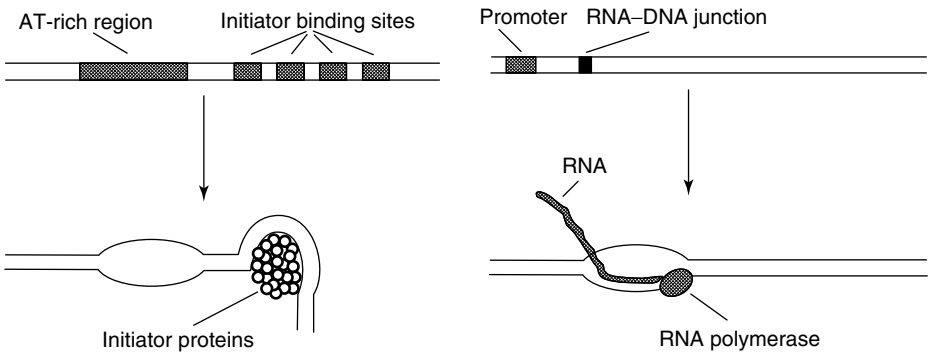
1.3.1 Initiation Mechanisms in Prokaryotes

A DNA segment carrying a replication origin can be isolated as a mini-replicon. DNA fragments can be linked to a selectable marker and introduced into the cell. Those fragments that allow for the maintenance of the marker are likely to contain an origin for autonomous replication of the DNA. Analysis of deletion and base-substitution mutants of the mini-replicon for their replication capacity will define a minimal region of the replication origin and essential motifs in that region. Replication origins that have been examined in this way can be classified into two groups from their structural similarities (Fig. 4). One class, to which most prokaryotic replicons belong, consists of 4 to 7 repeats of an initiator-protein binding site and an AT-rich region. The other group (ColE1 plasmid *ori*, T7 primary *ori*, T4 primary *oriA*) carries a transcriptional promoter instead of the initiator-protein binding sites.

The reconstitution of initiation in the test tube has elucidated several events during this process as follows: (1) recognition of the origin; (2) opening of a particular region in the origin; (3) loading of a replicative helicase onto the single-stranded DNA region, and (4) initial priming for leading- and lagging-strand synthesis. Some bacterial plasmids and phages are replicated unidirectionally. A major determinant for uni- or bidirectionality is the number of replicative helicases loaded at the origin. One helicase can form one replication fork. Thus, bidirectional replication involves two replicative helicases.

The initiation mechanism at the origin carrying the initiator-protein binding site has been depicted from studies on *in vitro* replication of *oriC* plasmid DNA (Fig. 4(a)). At least eight proteins are required for the *in vitro* reconstitution of the *oriC* minichromosome. A key event is the formation of the initial complex in which the initiator protein (DnaA protein) tightly binds to its 9 bp recognition sequence in *oriC*. Following this stage, an AT-rich region is opened in an ATP-dependent manner, and the DnaB helicase and SSB are loaded onto the single-stranded region to form the prepriming complex. Primase and DNA polymerase III holoenzyme then start the DNA synthesis. Several plasmids (F-factor and R-factor) and bacteriophages (λ, P1) in this class of replicon encode their own initiator proteins that specifically recognize and bind the origin sequence. Most of these origin-binding proteins can open the duplex DNA by themselves but fail to load the DnaB helicase. To do this, they contain one or two DnaA recognition sequences in their origins and utilize the DnaA protein as a landmark for entrance and activation of the replicative helicase.

Replicons without an initiator protein use transcription for origin recognition and duplex opening (Fig. 4(b)). Initiation of ColE1 plasmid replication requires RNA synthesis started 555 bp upstream from the transition point between RNA and DNA. The transcript (RNA II) forms an RNA–DNA hybrid around the transition point, is processed by RNaseH1, and serves as the initial primer for the leading strand DNA synthesis. DNA pol I extends the leading-strand DNA by about 400 nucleotides. This initial chain elongation, resulting in duplex opening, does not involve any helicase action but



(a) Origin with initiator-protein binding site (b) Origin with transcriptional promoter

Fig. 4 Two types of replication origins and related mechanisms of initiation.

requires that the template be negatively supercoiled. The loading of DnaB helicase is facilitated by primosome proteins, which are assembled into a complex on a specific DNA segment (primosome assembly site) about 150 bp downstream from the origin.

1.3.2 Initiation Mechanisms in Eukaryotes

The yeast *Saccharomyces cerevisiae* is the only eukaryote in which there is a detailed understanding of the sites used for initiation of chromosomal DNA replication. In yeast, these sites are called *ARS*s (autonomously replicating sequences) because they were initially identified by their ability to confer high-frequency transformation and self-replication on plasmids introduced into cells. By these criteria, there are 200 to 400 ARS elements in the yeast genome. ARS elements are relatively small, about 100 to 150 bp, and consist of one or more copies of an essential 11 bp-long AT-rich ARS consensus sequence, as well as several other less conserved elements. In other organisms, the sequences required to direct the initiation of DNA replication are more complex. In the fission yeast, *Schizosaccharomyces pombe*, initiation of replication requires origin sequences spread over at least 800 to 1000 bp. Although these sequences contain several AT-rich sequences of 20 to 50 bp that are important for origin function, they do not exhibit the strong sequence similarity observed for the *S. cerevisiae* ARS elements. Metazoan origins are still less well defined and can extend over thousands of base pairs of DNA. In addition, the sites of initiation are not always tightly linked within these regions.

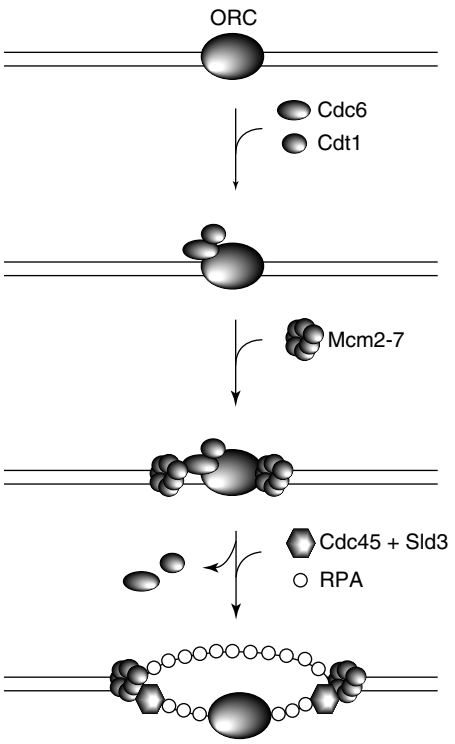


Fig. 5 Initiation mechanisms of eukaryotic DNA replication.

Eukaryotic origins of replication direct the formation of a number of protein complexes leading to the assembly of two bidirectional DNA replication forks. These events are initiated by the formation of the pre-replicative complex (pre-RC) at the origins of replication during G1 (Fig. 5). Pre-RC formation involves the ordered assembly of a number of replication factors including ORC, Cdc6, Cdt1, and Mcm2–7 proteins. The ARS consensus sequence is the binding site for the multisubunit origin recognition complex (ORC), which binds constitutively throughout the cell cycle and is essential for initiation. Several proteins are recruited to the ARS during the G1 phase of the cell cycle to form a pre-RC, including the multisubunit minichromosome maintenance (MCM) complex, which has ATPase and

helicase activity and is needed for both initiation and fork progression. The regulation of pre-RC formation is a key element of the mechanisms coordinating DNA replication with the cell cycle. Once formed, this complex awaits activation by at least two kinases that trigger the transition to DNA replication. As with the formation of the pre-RC, the transition to replication involves the ordered assembly of additional replication factors that facilitate unwinding of the DNA at the origin and culminates in the association of the multiple eukaryotic DNA polymerases with the unwound DNA.

2 Transcription

The transfer of information from DNA to protein begins with the synthesis of RNA molecules in a process called *transcription*. In this process of transcription, the genetic information carried in DNA is transferred to several kinds of RNA molecules (mRNA, tRNA, rRNA, and others), so that an mRNA encoding a polypeptide in its turn translates the information in the four-letter language of the nucleic acids to the twenty-letter language of the amino acids with the coordinated actions of tRNA and rRNA as part of the mechanism of protein synthesis.

2.1 RNA Polymerase and Transcriptional Apparatus

DNA-dependent RNA polymerase, which catalyzes the polymerization of RNA from ribonucleotides in a DNA-dependent manner, is the enzyme responsible for the transcription of DNA into RNA. The RNA polymerase binds to a specific DNA sequence, called the *promoter*, and unwinds the duplex DNA for about one turn of the helix to expose a short stretch of single-stranded DNA so that complementary base pairing can be made with the incoming ribonucleotides. The enzyme joins two of the ribonucleoside triphosphate monomers and then moves along the DNA strand, extending the growing RNA chain in the $5' \rightarrow 3'$ direction until it encounters a second special sequence, called the *terminator*, which signals where the RNA synthesis should stop. After the transcription is completed, each RNA chain is released from the DNA template as a free, single-stranded RNA molecule. In addition to RNA polymerase, other protein factors are required for efficient transcription, and they are responsible for determining the transcription efficiency of specific transcription units.

2.1.1 General RNA Polymerase Architecture

RNA polymerases are large multisubunit enzymes, which consist of 5 to 15 subunits and whose sizes are up to 0.6 MDa. In eubacteria and archaebacteria, a single type of RNA polymerase synthesizes all classes of RNA molecules, except for the primer RNA, which is synthesized by primase. The bacterial RNA polymerases consist of 5 subunits (2 α-subunits and one each of β, β', and ω), and a few more transcription factors, such as σ, ρ, and NusA for *E. coli* RNA polymerases, are required to initiate transcription from the proper start site in the promoter of duplexed DNA template (Table 2).

There are three known distinct types of RNA polymerases in eukaryotic cells. RNA polymerase I (pol I) makes ribosomal RNA and pol II mostly makes messenger RNA, while pol III makes small RNA molecules, such as transfer

[a] Mitochondria and chloroplast contain distinctive RNA polymerases.

RNA, 5S ribosomal RNA, and a few other small RNA molecules (Table 3). Among eukaryotic RNA polymerases, yeast *S. cerevisiae* RNA polymerases have so far been the most extensively characterized. Each RNA polymerase molecule consists of two large subunits, 160 $\sim$ 200 kDa and 130 $\sim$ 150 kDa, which share amino acid sequence homology with the β'- and β-subunits of the bacterial enzymes respectively, and a collection of smaller polypeptides. In pol II, Rpb3 and Rpb11 share amino acid sequence homology with the bacterial α-subunit, while Rpb6 shares a homologous sequence with the ω-subunit. Among the three types of eukaryotic RNA polymerases, five subunits (Rpb5, 6, 8, 10, and 12) are shared. pol I and pol III share two additional subunits (AC19 and AC40), both of which share amino acid sequence homology with the bacterial α-subunit.

As shown in Fig. 6, *S. cerevisiae* pol II and *Thermus aquaticus* RNA polymerase share a general architecture, which consists of five core subunits, β', β, α/α, and ω or their counterparts in the pol II (Table 4).

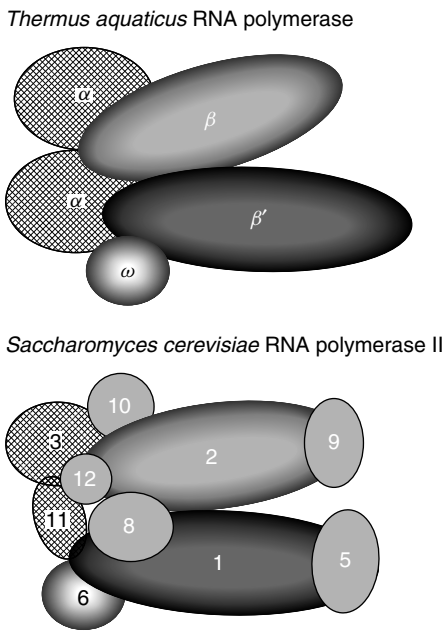

Fig. 6 General architecture of RNA polymerases. Schematic presentation for RNA polymerase subunits in bacterial (α, α, β, β', ω) and eukaryotic enzymes (Rbp1–12).

The bacterial β' and β subunits or the yeast Rpb1 and 2 subunits form the central masses with a deep cleft between them, respectively. α-homodimer in the bacterial enzyme or Rpb3–Rpb11 heterodimer in the yeast pol II anchor the two large subunits, while the fifth subunit ω and Rpb6 support and stabilize either the large subunit β or Rpb1.

2.1.2 Transcription Initiation

None of the eukaryotic RNA polymerases can initiate transcription by themselves; rather, they require a group of general transcription initiation factors for initiation at proper sites. pol II requires several general initiation factors (TFIIA, IIB, IID, IIE, IIF, IIH), and the formation of a functional preinitiation complex on the core promoters, which are defined as the minimal sequences required to recruit the appropriate RNA polymerase and initiate transcription, involves ordered

interactions of an array of general initiation factors on the core promoters (Fig. 7).

TFIID, a high molecular weight complex comprising TATA-binding protein (TBP) and more than 10 TBP-associated factors ($TAF_{II}s$), binds to the TATA box of the promoter; then TFIIA and B enter to form the DAB complex. The nonphosphorylated form of RNA polymerase II (pol IIa), together with TFIIF, binds to the DAB complex on the promoter, followed by association of TFIIE and TFIIH to form a closed preinitiation complex. The TFIIH XPB DNA helicase, composed

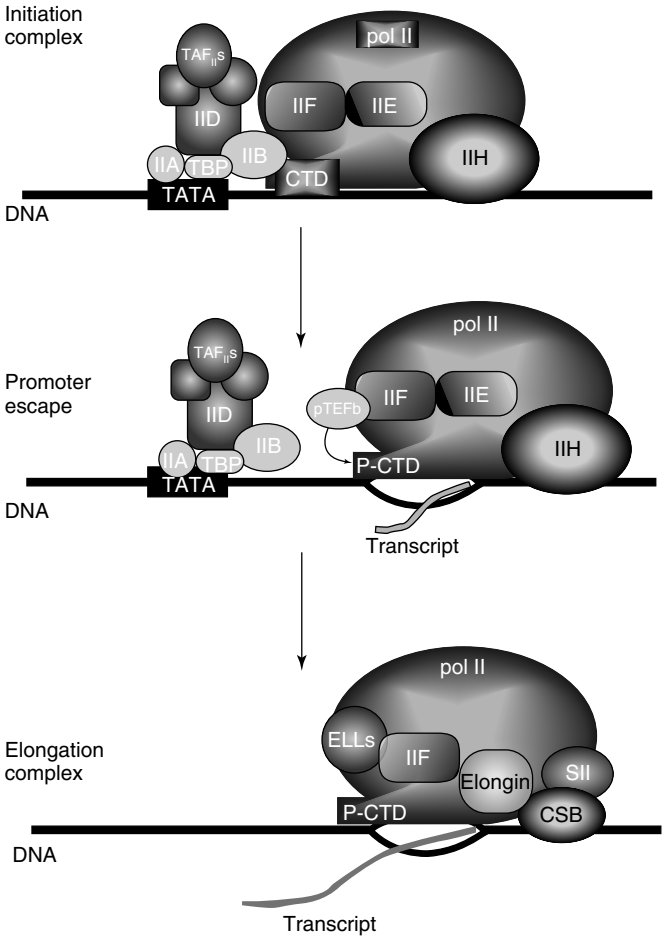

Fig. 7 Formation of a functional initiation complex on a TATA-containing promoter by general initiation factors. After completion of the final initiation complex, pol II initiates transcription and moves away from the promoter and dissociates from the DAB complex after synthesizing 10- to 15-nucleotide-long transcripts (promoter escape). During the promoter escape step, the elongation complex is released from the promoter to start elongation by phosphorylation of the CTD by pTEFb. P-CTD: phosphorylated CTD.

of nine subunits, and two of which, XPB and XPD, are catalytic subunits for the DNA helicase, converts the closed preinitiation complex to both an initiation- and an escape-competent transcriptional intermediate (an open complex) in a single ATP-dependent step, probably by unwinding the DNA downstream from the transcription start site, and the synthesis of the first phoshodiester bond of nascent transcript begins.

RNA polymerase III requires different combinations of transcription initiation factors to form a preinitiation complex on the promoters of 5S RNA, tRNA, and other small RNA genes. Three pol III specific initiation factors, TFIIIA, B, and C, are required for transcription of the 5S RNA genes, TFIIIB and C for the tRNA genes, and TFIIIB and TFIID for the U6 gene. TFIII A and C, as well as TFIID, recognize and bind to specific DNA elements while TFIIIB has by itself no sequence–specific interaction with DNA. RNA polymerase I also requires several transcription factors to form an active initiation complex on the promoter of rDNA.

2.1.3 Promoter Escape

After initiating transcription, pol II moves away from the promoter and dissociates from the DAB complex after synthesizing 10- to 15-nucleotide-long transcripts (promoter escape, Fig. 7).

The largest subunit of pol II (Rpb1) contains an unusual repetitive domain, which is not found in the homologous large subunits of pol I and III or in the bacterial β'-subunit. This carboxyl-terminal domain (CTD), called the *tail* of pol II, consists of multiple heptapeptide repeats of the consensus sequence YSPTSPS. The heptapeptide sequence is found in the largest subunits of most eukaryotic RNA polymerase II. The deletion of most or all of the CTD is lethal for yeast, *Drosophila*, and mouse cells, thereby indicating that the CTD has an essential role in transcription. The CTD of RNA polymerase II in the initiation complex is hypophosphorylated, while pTEFb (positive transcription elongation factor b), a cyclin-dependent CTD kinase complex composed of CDK9 and one of several cyclins such as T1, T2, and K, highly phosphorylates the CTD during the step of promoter escape, and thus promotes a dissociation of the elongation complex of pol II from the DAB complex.

2.1.4 Transcription Elongation

During RNA chain extension, RNA polymerase II forms a stable elongation complex, and in the complex downstream DNA duplex enters the enzyme between a pair of mobile ''jaws'' formed by Rpb1, Rpb5, and Rpb9 subunits and then extends through the cleft toward the active site for RNA synthesis with Mg^{2+}. The DNA–RNA hybrid extends upward beyond the active site and the template strand is locked near the catalytic site in place by a clamp formed by parts of, Rpb1, Rpb2, and Rpb6. In the active site, the nontemplate strand of DNA is held within the Rpb2 subunit and the RNA transcript; it then extrudes through the complex via a channel formed by parts of both of the two large subunits, and the growing RNA end is located above the pore/secondary channel, from which nucleoside triphosphates (NTPs) may be supplied during RNA synthesis (Fig. 8).

mRNA synthesis is carried out efficiently in eukaryotic cells at rates of 1200 to 1500 nucleotides/min. However, purified mammalian pol II extends the RNA chain *in vitro* at rates of only 300 to 400 nucleotides/min, thus indicating

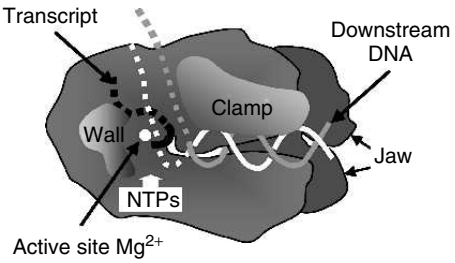

Fig. 8 The RNA polymerase II elongation complex. During transcript (black line) extension, RNA polymerase II forms a stable elongation complex in which a downstream DNA duplex (gray lines) enters the enzyme between a pair of mobile ''jaws'' and extends through the cleft toward the active site for RNA synthesis. The DNA–RNA hybrid extends upward beyond the active site and the template strand (white line) is locked near the catalytic site. The pore/secondary channel where the nucleoside triphosphates (NTPs) enter is shown.

that the elongation step of RNA synthesis by eukaryotic RNA polymerase II *in vivo* has to be supported by various transcription factors or elongation factors to achieve higher rates of elongation. Furthermore, unusual template structures, damage on the template, or imbalance in the cellular ribonucleotide pool, which cause either a pause or an arrest of transcription, can be overcome by factors that directly or indirectly interact with the elongation complex. Pausing occurs when RNA polymerase II undergoes modest and reversible backsliding on the DNA template, thus resulting in a misalignment of 3′-OH terminus of the nascent transcript with the catalytic site, while irreversible backsliding of the enzyme causes arrest since the misalignment becomes even more severe.

Elongation factors fall into two broad functional classes based on their abilities to either prevent transient pausing by pol II or reactivate arrested pol II. The majority of elongation factors including ELLs, Elongin, and CSB are capable of suppressing transient pausing by pol II. TFIIF, one of the general transcription factors also has an activity to suppress transient pausing. In addition, the phosphorylation of the pol II CTD by pTEFb is required to support the efficient elongation by pol II, as well as for the promoter escape, as described above (Fig. 7).

Among many elongation factors, only the SII family elongation factor has a capacity to reactivate the arrested pol II by triggering the polymerase-associated endoribonuclease that cleaves the nascent transcript upstream of its 3′-OH terminus, thus resulting in the formation of a new 3′-OH terminus. The newly generated 3′-OH, which is correctly positioned to the catalytic site of the enzyme, can thus be reextended.

During transcript elongation, pol II is hypothesized to face a major obstacle-nucleosome in which the DNA is tightly wrapped into the chromatin. It is likely that a class of chromatin elongation factors, such as an elongator, alters the structure of the nucleosome through histone acetylation, chromatin remodeling, and histone dissociation, thereby facilitating the elongation step by pol II.

2.2 Transcription Unit

Transcription takes place in limited regions of genomic DNA, and only one of the two DNA strands is used as a template. The promoter, an oriented DNA sequence along the template DNA, determines the startpoint of the region to be

transcribed and also determines which of the two strands is copied. A transcription unit extends to the terminator, at which the RNA polymerase stops adding nucleotides to the growing RNA chain. The critical feature of the transcription unit is that it constitutes a stretch of DNA expressed via the production of a single RNA molecule. A transcription unit may include only one or several genes. A typical transcription unit of *E. coli* and various transcription units for three eukaryotic RNA polymerases are shown in Fig. 9.

2.2.1 Bacterial Transcription Unit

Bacterial promoters are identified by two short conserved sequences centered at −35 and −10 relative to the startpoint. In *E. coli*, TTGACA and TATAAT are consensus sequences for the −35 and the −10 boxes of the promoters, respectively, which are recognized by the RNA polymerase holoenzyme carrying σ^{70}. Promoters whose −10 and −35 sequences closely approximate the consensus sequences are strong promoters, and the distance separating the two sequences, usually 16 to 18 bp, is also important. Bacterial RNA polymerase terminates transcription at two types of sites; factor-independent sites contain a GC-rich hairpin followed by a run of U residues, while ρ factor–dependent termination requires ρ-specific sequences.

2.2.2 Eukaryotic Transcription Unit

In eukaryotes, the promoters recognized by each type of RNA polymerase are distinct. The promoters for RNA polymerase I are located upstream from the transcription startpoint, and the sole product of transcription by pol I is a large precursor that contains the sequences of the major rRNA (28S, 5.8S, 18S). Termination occurs at a discrete site and apparently requires few factors.

The promoter elements that are necessary and sufficient for the specific initiation by RNA polymerase II with its general factors are referred to as either minimal or core promoter elements, and are located around the transcription startpoint. The most common core elements are the TATA box, which is present about 20 to 30 bases upstream of the transcription start site, the initiator element (Inr) located at the start site, and a downstream promoter element (DPE), which is present about 30 bases downstream of the transcription start site. Specific genes may contain at least one or all of these elements, which may function in conjunction with other cis-elements such as UAS (upstream activating sequence) or enhancers, which positively regulate transcription initiation.

The termination capacity of RNA polymerase II is regulated through the polyadenylation of the transcript. The signal sequence for polyadenylation, AAUAAA, is located 10 to 30 nucleotides upstream of the polyadenylation site, which is often immediately after the dinucleotide 5′-CA-3′ and is followed 10 to 20 nucleotides later by the GU-rich region. When the elongation complex of pol II, to which the cleavage and polyadenylation specificity factor (CPSF) and the cleavage stimulation factor (CstF) bind through the CTD, transcribes across the polyadenylation signal sequence, CPSF binds to the signal sequence and CsTF binds GU-rich sequence on the transcript. Next, the transcript is cleaved to create a new 3′ end, to which the poly (A) tail is added by poly(A) polymerase associated with the bound CPSF and CstF, followed by the termination of transcription.

For RNA polymerase III, there are two types of promoters: the promoters for U6

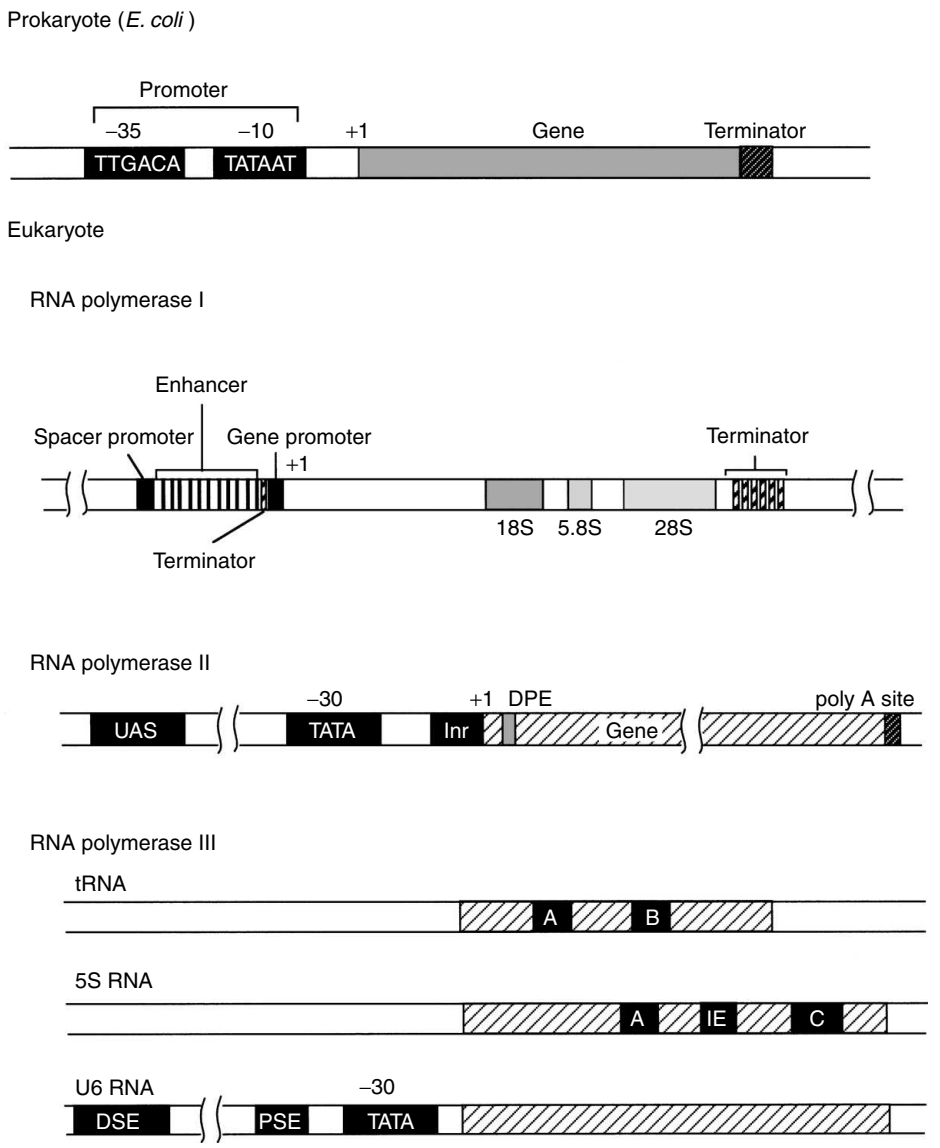

Fig. 9 Various types of transcriptional units in prokaryotic and eukaryotic cells. Inr, the initiator element; UAS, upstream activating sequence; DPE, a downstream promoter element; A, B, IE, C, intragenic cis-elements in genes for tRNA and 5S RNA; DSE, the distal sequence element; PSE, proximal sequence element.

are upstream from the startpoint, while those of the 5S RNA and tRNA genes lie downstream from the startpoint. The external promoter for the U6 gene consists of the TATA box and the distal and proximal sequence elements (DSE and PSE), which enhance promoter activity. Intragenic A and B boxes in the tRNA

gene or the B box in the 5S RNA gene can both be recognized by, and bound by, TFIII C, while the IE and C boxes in 5S RNA are involved in interaction with TFIIIA. Transcription by RNA polymerase III terminates within a run of 4 U residues embedded in a GC-rich region, in a manner similar to that observed in the prokaryotic factor-independent terminators.

2.3 Regulation of Transcription

Transcriptional regulation is the primary means of controlling gene expression, and it is essential for the developmental program of multicellular organisms, as well as for the switching on and off of gene expression in response to intra- or extracellular signals. In any organism, RNA synthesis can be regulated by mainly controlling the efficiency of initiation.

2.3.1 Transcriptional Regulation in Bacteria

In bacterial cells, there are several different mechanisms by which the modulation of transcription initiation is achieved. Various σ-factors modify the binding ability of RNA polymerase to specific promoter sequences, thus enabling it to initiate at a different set of promoters.

In a set of genes whose expression is coinduced in response to intra- or extracellular signals, a common repressor protein binds to specific DNA sequences, called an *operator*, in a group of promoters and represses their transcription by inhibiting RNA polymerase binding to the promoters. After responding to a specific signal, such repressor molecules are inactivated, and the RNA polymerase can thereby initiate transcription from the promoters. For example, the LexA protein, which represses the SOS-regulon, is proteolytically inactivated by an activated form of the RecA protein in response to DNA damage. The modulations of genes (an operon) involved in the biosynthesis of a specific metabolite are mediated by the repressors that directly sense the intracellular status of the product. For example, the LacI repressor protein binds to the operator region of the *lac* operon promoter in the absence of lactose or its metabolite, thereby prohibiting transcription initiation on the promoter, and it dissociates from the promoter after binding to a metabolite of lactose, thus allowing for the transcription of the *lac* operon.

Promoters requiring positive activator proteins for efficient expression are characterized by a poor fit to the consensus sequence in the −35 region. The protein activators bind to the region near the −35 box, and stimulate initiation either by improving the affinity of RNA polymerase for the sequence or by increasing the rate of isomerization of the initiation complex. The complex of cAMP with catabolite activator protein (CAP) enhances the affinity of RNA polymerase to the *lac* promoter about 20-fold. Ada-protein-accepted alkyl groups from DNA damaged by alkylating agents as a repair reaction, in turn, strongly bind to Ada boxes in the promoters of Ada regulon, such as *alkA, aidB* and *ada* itself, and enhance the affinity of RNA polymerase to the promoters, thus establishing an adaptive status to the alkylating agents.

In addition to the regulation of initiation, the level of transcription can be regulated by the premature termination of transcription or attenuation. For example, in most bacterial amino acid biosynthesis operons, an early termination of transcription occurs at the attenuator site that lies from 100 to 200 bases downstream of the start site, when an abundance of the charged

cognate tRNA signals a sufficiency of the amino acid. Attenuation in these operons is regulated in a complex mechanism involving charged cognate tRNA, ribosome, and ρ-protein.

2.3.2 Transcriptional Regulation in Eukaryotes

In multicellular organisms, each cell selects a set of genes from their genome to be expressed at a given time and under specific stimuli, and this selectivity and specificity of gene expression is a fundamental mechanism for controlling the cell fate such as cell proliferation, differentiation, and cell death as well as cellular functions. In eukaryotic cells, transcription by RNA polymerase II, a process for the synthesis of mRNA encoding polypeptides, which are major determinants of diversity of each cell, is regulated more dynamically than transcription by pol I and III that provide rather common elements, such as rRNA and tRNA for cell function.

The genes in the nuclear genome are usually packaged into chromatin consisting of nucleosomes and other chromatin proteins, and their promoters are transcriptionally inactive because of their limitations for access by the transcription apparatus (Fig. 10). An assortment of regulatory elements for RNA polymerase II transcription can be scattered both upstream and downstream of the transcription start site for a gene. Each gene has a particular combination of positive and negative regulatory cis-elements that are uniquely arranged regarding the number, type, and spatial array. Usually, cis-elements are arrayed within several hundred base pairs of the initiation site, but some elements can exert their control over much greater distances (1 to 30 kb). These elements are binding sites for sequence-specific DNA binding proteins, such as AP-1 (JUN/FOS heterodimer), that either directly or indirectly mediate activation or repression of transcription of the gene. The region near the startpoint, in particular the TATA box (if there is one), is responsible for selecting the exact startpoint and it is called the *promoter*, as described above. The elements further upstream determine the efficiency with which the promoter is used and are known as *UAS* (*upstream activating sequence*) or enhancers (Fig. 9).

In order to transcribe a particular gene, the chromatin structure has to be remolded, thus enabling various DNA binding proteins and transcription apparatuses to access a particular promoter (Fig. 10). First, inactive genes are localized to condensed chromatin domains or so-called heterochromatin compartments, in which each promoter is assembled in regularly spaced nucleosomes. A sequence-specific DNA binding protein binds to a particular cis-element, and then recruits a specific chromatin-remodeling complex such as SWI/SNF with other proteins through protein–protein interaction. The chromatin-remodeling complex alters the twist and writhe of nucleosomal DNA thereby affecting its accessibility to DNA binding proteins. Following chromatin remodeling, the prebound protein or another DNA binding protein on the second cis-element recruits another class of chromatin modifiers with histone acetyltransferase (HAT) activity, such as PCAF (p300/CBP-associated factor), CBP (CREB binding protein), and p300. HATs acetylate specific lysine residues in histone amino–termini and weaken the interactions between the histone octamer and DNA, thus further facilitating decondensation of nucleosome structure. The retention of SWI/SNF complex on nucleosomal promoter is significantly stabilized by histone acetylation.

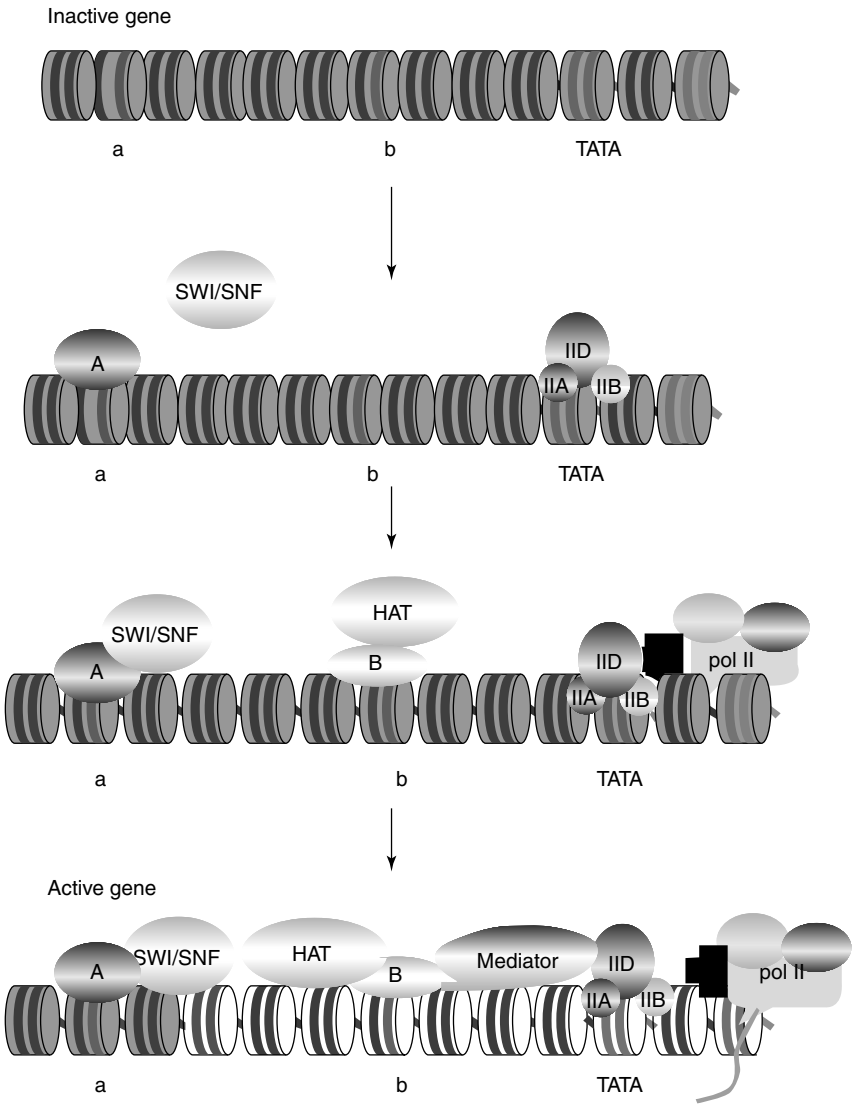

Fig. 10 Transcription activation in eukaryotes. Genes in the nuclear genome are usually packaged into chromatin consisting of nucleosomes and other chromatin proteins. In order to transcribe a particular gene, the chromatin structure has to be remolded, and thus various DNA binding proteins (A and B) can bind cis-elements (a and b) and further promote the formation of the transcription initiation complex on a particular promoter (TATA).

In addition to the acetylation of histones, phosphorylation and methylation of histones or non-histone proteins are likely to play important roles in both chromatin modification and control of gene expression.

Either during or after the remodeling or modification steps of chromatin, a

partial initiation complex (TFIIA/B and TBP) or a complete initiation complex (TFIIA/B, TBP/TFIID, and pol II) with other general factors are recruited. Again, the assembly of the initiation complex is facilitated through histone modification by the promoter-targeted HAT. Finally, a mediator complex such as DRIP, ARC, TRAP, and/or coactivator such as p300/CBP or p160/SRC are recruited to the initiation complex through protein–protein interaction with DNA binding proteins such as CREB or nuclear receptors, which specifically bind to one of the cis-elements on the promoter. The mediator or coactivator is likely to be a bridge between a given DNA binding protein or activator and pol II via direct associations with specific subunits of the complex, thus ensuring the formation of a functional preinitiation complex on the core promoter.

The repression of a certain gene expression is also regulated through the modification of chromatin by histone deacetylases (HDACs), which remove acetyl groups at lysine residues in histones, which are transfered by HATs. The deacetylation of histones causes a particular region of chromatin to be condensed as heterochromatin, which thus results in the repression of gene expression.

Keywords

AmpFLP (Amplified Fragment Length Polymorphism)
A technique based on PCR amplification of specific VNTRs with core repeats ranging between 8 and 70 bp in length, using sequence-specific oligonucleotide primers that flank the tandem repeat regions. This strategy generates discrete profiles of amplification products (amplicons) that correspond to the alleles of the locus. Profiles with one band are denoted as homozygous. Profiles with two bands are scored as heterozygous.

AP-PCR (Arbitrarily Primed Polymerase Chain Reaction)
A variation of the RAPD strategy (see below) wherein discrete amplification patterns are generated using single oligonucleotide primers 10 to 50 nucleotides in length to amplify genomic DNA by PCR. In the first two cycles of amplification, annealing of the primers is carried out under nonstringent conditions to allow the primers to anneal to multiple regions along the DNA template. The method generates multiple band patterns.

DAF (DNA Amplification Fingerprinting)
Another variation of the RAPD technique wherein single oligonucleotide primers of arbitrary sequence as short as five nucleotides in length are used to amplify DNA by PCR. This technique also generates multiple band profiles.

ISSR (Inter Simple Sequence Repeat)
In this technique, nucleotide sequence information from microsatellite regions (simple sequence repeat elements) is used to design oligonucleotide primers that will serve to amplify regions of DNA mapping between microsatellites (SSRs). An anchor made up of a stretch of degenerate nucleotides (between 3 and 10 nucleotides) is also attached either at the 5′ or 3′ end of the primers to increase the specificity of the amplification process. This technique generates complex multiple band patterns typically consisting of more than 200 band signatures.

Microsatellites and Minisatellites
Microsatellites are nucleotide sequence elements composed of tandemly repeated core repetitive sequence blocks of 2 to 7 bp in length distributed throughout the genomes of higher eucaryotes. Minisatellites are similar in nature but are composed of 8 to 70 bp core repeat sequences.

RAPD (Random Amplified Polymorphic DNA)
A procedure used to detect nucleotide sequence polymorphisms in DNA using a single primer of arbitrary nucleotide sequence. PCR generates several discrete amplification products when a single primer (10 to 21 bases in length) is designed to anneal, in forward and reverse orientations, to two different sites on DNA within a distance that allows amplification.

Sequencing
A method used to determine the sequence (linear order) of nucleotide bases along a strand of DNA.

SNP (Single-nucleotide Polymorphism)
Variation between individuals at certain nucleotide base positions within the genome. SNPs may arise as a consequence of single-nucleotide substitution, insertion, or deletion.

STR (Short Tandem Repeat)
Also referred to as *simple sequence repeat* (SSR) or *microsatellite*. STRs are tandem repeat regions 2 to 7 bp in length, scattered throughout genomes. PCR procedures are routinely used to amplify these regions for the generation of distinct allelic profiles.

VNTR (Variable Number of Tandem Repeats)
Regions of the genome that contain a variable number of end-to-end duplications of a series of identical or almost identical nucleotide sequence motifs (typically between 2 and 70 bp each). The number of tandem repetitions translates into length polymorphisms that characterize the allele profile for a given genomic region (locus).

DNA typing analysis consists in generating and interpreting allelic profiles for the purpose of identifying an individual, a representative from a given group or species, or to determine the origin/provenance of biological material such as cells, clinical specimens, and forensic evidence. The process capitalizes on length differences or sequence variations (collectively referred to as *polymorphisms*) associated with discrete regions within the genomes of living organisms. These genetic differences are examined using a variety of DNA profiling strategies that utilize different modes of detection to reveal the polymorphic nature of the target DNA segments. The choice of method adopted is largely dictated by the nature, quantity, and physical state of the sample to be identified. Each of these considerations, in addition to the current state of knowledge regarding the sequence, structure, and organization of an organism's nuclear and organelle genomes, will also determine what type of polymorphisms can be surveyed. Polymorphic allele patterns can be represented as bar code–like profiles, peaks on tracings, photographic bars or dots on X-ray films, or colored spots on solid supports or computer monitors. DNA typing can be applied to any biological material that contains DNA such that current applications reach across every taxonomic kingdom.

DNA typing analysis is particularly powerful because no two individuals or strains, with the exception of genetically identical twins and clones, share the same allele complement for multiple polymorphic loci. In addition, with the advent of DNA typing strategies based on the polymerase chain reaction (PCR), investigators have advanced beyond conventional restriction fragment length polymorphism (RFLP) analysis and can carry out reliable, accurate, precise, and sensitive identifications from only minute quantities of starting biological material. This, coupled with the surprising chemical stability and longevity of DNA, has had a major impact in forensic science for the resolution of violent crimes or the identification of human skeletal remains from the scenes of mass disasters. Today, DNA typing analysis is employed in almost every discipline under the biological sciences. It continues to prove instrumental to studies on human origins and diversity, in clinical medicine to resolve the identity of specimens, ascertain the provenance of transplantable tissues and organs, and expedite the identification of viral and microbial pathogens, and in guiding the manner in which animal, plant, and insect breeding programs are being conducted and followed.

This article describes the general principles underlying DNA typing analysis, summarizes and compares currently available methods for specimen identification, and provides an overview of applications in the field of forensics and the biological sciences.

1 Principles

1.1 DNA Types and Regions of Variability Relevant to Individual Identification

With the notable exception of the RNA viruses, DNA constitutes the molecule of heredity in all living organisms. In eucaryotes, the majority of a cell's genetic material and gene set (genome) resides in the nucleus and is referred to as *nuclear genomic DNA*. Plants and animals also contain organelles – chloroplasts (restricted to plants) and mitochondria – with their own genomes. In procaryotes, the sum total of genomic DNA is not confined to a nuclear compartment but rather is attached to the inner side of the cell membrane as a nucleoid.

DNA typing analysis relies on genetic variations that manifest themselves as tandem arrays of repetitive sequences or single-nucleotide sequence polymorphisms. Tandem repeats of repetitive DNA sequence blocks detected in human nuclear genomic DNA are generally subdivided into minisatellites and microsatellites according to the size of the core repeat unit and to the overall length of the tandem array. Similar subsets of tandem repetitions have been detected and characterized in the nuclear genomic DNA of other animals and plants. Depending on the DNA region (or locus), each repeat element can consist of a minimum of 2 to perhaps 70 bp. The number of tandem repetitions for each allele, on the other hand, can vary from one to several hundred – hence their collective designation as ''variable number of tandem repeats

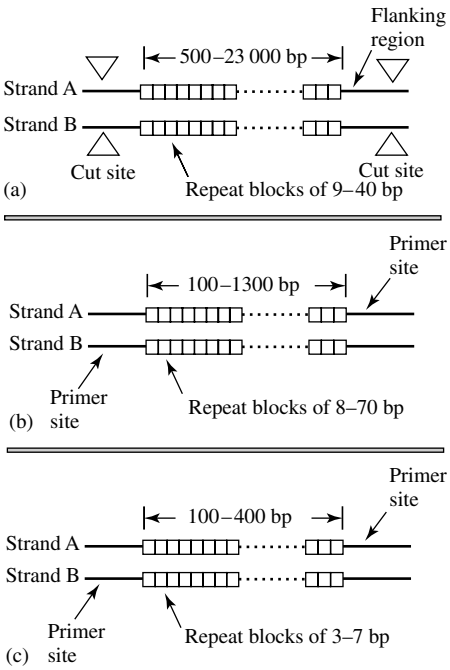

Fig. 1 Three types of VNTR polymorphisms routinely detected in human nuclear genomic DNA: (a) restriction fragment length polymorphism (RFLP), (b) amplified fragment length polymorphism (AmpFLP), and (c) short tandem repeat (STR) polymorphism. For all three types of length polymorphisms, the ability to distinguish one individual from another depends on the variations in the number of tandem repeat elements present in each of the alleles of a particular locus or genomic region. VNTRs detected by the RFLP approach are attributed to repetitive nucleotide sequence blocks ranging between 9 and 40 base pairs (bp) in length that are repeated 60 to 450 times in tandem. DNA segments containing VNTRs are produced after digestion with a site-specific restriction enzyme (i.e. *Hae*III) that cleaves within the regions immediately flanking the VNTR. The procedure generates allelic DNA segments in the range of 500 bp to 23 kb in size. Because of their large size, VNTR-containing DNA fragments cannot be amplified by PCR and must be resolved by conventional agarose gel electrophoresis. By contrast, VNTRs detected by the AmpFLP approach are considerably smaller and consist of repeat blocks typically ranging between 8 and 70 bp and repeated 10 to 40 times, depending on the allele. AmpFLP VNTRs can be generated by PCR amplification with specific VNTR-flanking oligonucleotide primer pairs. This process routinely yields DNA size fragments (i.e. amplicons) of 100 to 1300 bp in size that are easily resolved on polyacrylamide gels. STRs, on the other hand, arise from repeat blocks in the 3- to 7-bp range, which are repeated 6 to 44 times in tandem. Because of their small overall repeat lengths – typically in the range of 100 to 400 bp per allele – STR loci lend themselves readily to PCR amplification either alone or as combinations using several locus-specific primer pair sets in a process known as ''multiplex PCR'' and to automated high-throughput analysis. STR amplicons are best resolved by polyacrylamide or capillary gel electrophoresis. [Modified from Duncan and Tracey (1997).]

(VNTRs)'' (Fig. 1). Investigators rely on these length variations to construct DNA allele profiles. This can be achieved by restriction fragment length (RFLP), amplified fragment length (AmpFLP), or short tandem repeat (STR) polymorphism analysis. The extent of length variation across the allele set for a given locus provides a measure of the usefulness of the VNTR for identification purposes. Thus, the greater the variation encountered within a population of individuals, the greater the ''polymorphism information content'' and consequent utility of the VNTR locus. For the study of VNTRs, DNA regions containing different numbers of tandem repeats

digested with a restriction endonuclease or amplified by PCR are fractionated by size using electrophoresis through a sieving medium such as agarose (RFLP) or polyacrylamide (AmpFLP and STR). Following electrophoresis and processing for detection, the relative positions of bands corresponding to distinct alleles are determined relative to known DNA size standards. By combining several polymorphic loci in a single analysis, investigators can obtain very high ''powers of discrimination'' (i.e. a statistical measure of the unique character of the genetic profile generated from the biological sample).

Recent genomic mapping and sequencing initiatives in humans and other organisms have identified single-nucleotide polymorphisms (SNPs) as one of the most common forms of genetic variation among individuals. SNPs account for approximately 85% of all known polymorphisms in the human genome and are more frequent than microsatellite markers. They occur on average every 1000 nucleotide positions as opposed to every 300 to 500 kbp for microsatellites. The large size of the human nuclear genome (6.2×10^9 bp) predicts the existence of millions of SNPs and thousands of microsatellite markers. Individual SNPs, however, are either detected or altogether absent and are consequently less informative than VNTR markers. Nonetheless, this simple ''biallelic'' variation greatly facilitates high-throughput analysis and detection using DNA microarrays. Recent estimates suggest that a subset of 50 to 100 SNPs could be used to achieve the same power of discrimination as that provided by the 13 STR core loci currently in use by the majority of forensic DNA laboratories in North America and Europe.

SNP typing of organelle genomic DNA like that of the mitochondrion (mtDNA) provides yet another means to help establish the identity of biological specimens of human and other animal species origin. In humans, the exercise exploits nucleotide sequence variations within two hypervariable regions (HV1 and HV2) of the noncoding section (known as the *mitochondrial control region* or *D-loop*) of the mtDNA genome. In other animals, species identification has been achieved using the mitochondrial cytochrome b, 16S, and 12S ribosomal DNA (rDNA) nucleotide sequences. MtDNA analysis constitutes a very sensitive assay because thousands of copies of the comparably small mtDNA circular genome (16 500 bp) are present in each somatic cell as opposed to two copies (one maternal, the other paternal) of nuclear genomic DNA. MtDNA is also reported to be more resistant to degradation by cellular enzymes or enzymes secreted by microorganisms located in the vicinity of the biological specimen. Because mtDNA polymorphisms are detected within much smaller segments of DNA, this technique is more successful on highly degraded specimens (i.e. aged skeletal material, mummified soft tissue and hair shafts, sterilized canned foods, charred fragmented bones). MtDNA is maternally inherited and does not undergo recombination thereby increasing the range of reference material available for the identification of human remains (i.e. distant maternal relatives become potential reference sources for comparison). Although nuclear genomic DNA profiling is highly informative and represents the method of choice for the majority of DNA identification requirements, mtDNA analysis is recognized as a validated, robust, reliable, and well-established DNA profiling system for some of the most challenging and degraded samples such as archeological

and mass disaster specimens, where nuclear DNA profiles are either impossible to obtain or uninformative.

DNA typing in plants using chloroplast genomic DNA is becoming more frequent. Chloroplasts are found in large numbers within each plant cell. Chloroplasts are protected by the plant cell wall and by the plant cell and organelle lipid bilayer membranes such that chloroplast genomic DNA tends to resist breakdown from microorganisms and environmental insult. Nucleotide sequence variations recorded within the transfer RNA gene complex of the chloroplast genome have been successfully applied to the identification of plant species.

1.2 Specimen Processing

In principle, and largely as a result of significant advances in PCR amplification strategies, any living or nonliving biological specimen or material containing minute quantities of relatively intact DNA fragments can be used for DNA typing analysis. At present, severely degraded samples containing DNA, no longer than 60 to 100 bp in length, can be analyzed. Until very recently, common sources of DNA routinely processed for medical and forensic applications included blood, saliva, semen, solid tissues, plant foliage, and seeds. With PCR, however, the list of samples submitted for DNA testing has been expanded to include bone, teeth, hair, epithelial cells from the skin, and even sweat from human or other animals. In addition, forensically relevant specimens such as fingernails, cigarette butts, chewing gum, bite marks on food items, licked envelope flaps and stamps, and handled objects such as telephone receivers, wine glasses, beverage cans, and beer bottles (all of which can be swabbed to collect transferred epithelial cells) have become amenable to analysis. Other samples such as human and animal feces, urine, and sputum as well as canned foods can also constitute rich sources of DNA.

Biological samples destined for forensic DNA analysis are often subjected to a variety of environmental insults. Consequently, these samples create a special challenge and it is often only following collection that conditions can be controlled to preserve the integrity of the specimens. Ensuring the integrity of clinical or forensic samples is best achieved by cold storage [freezer (−20 °C or − 70 °C) or liquid nitrogen] in clean, dry environments. Such conditions reduce contamination by microorganisms and the likelihood of degradation of DNA by cell lysis and DNAase activity. Alternatively, specimens such as bones or tissues can be immersed in preservation solutions at the site of collection and stored at room temperature for prolonged periods of time before being processed for DNA analysis. Biological samples (blood, buccal swabs, or hair) such as those destined for inclusion in convicted offender DNA data banks can be collected by direct deposition on specially treated filter paper (i.e. FTA® paper; Fitzco Inc., Minneapolis, MN, USA) that inhibits the growth and biological properties of bloodborne pathogens (e.g. HIV and hepatitis B and C) and stabilizes DNA for long-term storage7 at ambient temperatures.

Various DNA extraction procedures can be used to obtain essentially pure preparations of high molecular weight DNA in good yields from human or animal tissues. Although specific DNA extraction procedures are required for bones, teeth, and hair, the enzyme proteinase K is generally used to promote cell lysis and digest proteins in a sample in the presence of

the detergent sodium dodecyl sulfate. Digested proteins, lipids, and other debris and contaminants can be removed by organic extraction using a mixture of phenol and chloroform. Traces of residual phenol are removed by extraction with chloroform and isoamyl alcohol. High molecular weight DNA is then recovered in essentially pure form (although RNA may also be present without consequence to the final analysis) by ethanol precipitation in the presence of salt. An alternative method for collecting phenol-extracted DNA consists in selective ultrafiltration through special membranes (Centricon-100 or Microcon-100 ultrafiltration cartridges; Amicon Corp., Beverly, MA) that concentrate DNA while removing impurities by centrifugal dialysis. DNA obtained by the organic extraction method is double stranded and is therefore compatible with both RFLP and PCR-based procedures.

Other methods that bypass organic extraction for the recovery of DNA from cell lysates include (1) selective capture of DNA on magnetic beads followed by elution in a buffered solution and (2) the use of cation-exchange resins such as Chelex 100 to bind and partition positively charged molecules from cell lysates on the resin and allow the negatively charged DNA to remain in solution. Both these methods are only compatible with PCR-based assays because cell lysis is carried out at elevated temperatures (95 °C and 100 °C), which result in the denaturation of DNA to its single-stranded form.

Disruption of plant cells to release DNA poses a special challenge. Plant tissues differ from those of animals in that they are surrounded by rigid lignin-rich cell walls that are very difficult to lyse. Methods optimized to obtain the best yields and the purest DNA preparations possible typically involve further purification steps to remove phenolic substances, polysaccharides, and humic acids that are often present along with DNA and can inhibit downstream restriction enzyme digestion and PCR amplification reactions.

When biological samples are collected and stored on small, designated areas of FTA® paper (microbial, animal and plant cell cultures, blood, hair bulb cells, buccal swabs), deposited cells are lysed on contact with the chemicals present in the paper. The DNA remains trapped between the fibers and is subsequently purified by washing away the chemical components and cellular debris that could inhibit subsequent assays. The washed immobilized DNA can be recovered on circular punches (1.2 mm, 2 mm, or 3.7 mm in diameter) and transferred directly into a microcentrifuge tube or a 96-well assay plate. This simple procedure allows automation of sample preparation for PCR amplification with robotic workstations. In addition, the use of the FTA® paper represents a simple and inexpensive approach to long-term storage or archiving of biological samples at room temperature.

Some DNA extraction methods have been designed to address special circumstances. In forensic investigations, for example, the analyst may be presented with specimens containing mixtures of male and female cells such as in the case of oral, vaginal, and anal swabs obtained from sexual assault victims where sperm and female epithelial cells are often present. To separate the male and female cells from one another, specific DNA extraction methods are used. The standard ''preferential lysis'' method exploits the different resistance properties of sperm and vaginal cells against proteolytic digestion. The female cells are lysed in extraction buffer lacking the reducing agent dithiothreitol (DTT), and the DNA is isolated from the

supernatant. The remaining sperm pellet is then lysed by adding extraction buffer supplemented with DTT and detergents, which release the male DNA into the solution, and allows for subsequent isolation and concentration. Recently, enriched male cell fractions have been obtained using methods such as fluorescence activated cell sorting (FACS), which takes advantage of differences in the cell size, shape, surface antigen properties, and DNA content (haploid for spermatocytes, diploid for vaginal cells). Another approach used to enrich for male cells consists in capturing sperm cells using specific antibodies raised against sperm head or tail antigens, which have been covalently linked to magnetic beads. Following washes to remove cellular debris and contaminating female cells, the male cells can be eluted and processed for DNA typing.

The integrity of a DNA preparation can be estimated by visual inspection with the help of ultraviolet light following agarose gel electrophoresis and staining with intercalating dyes such as ethidium bromide and SYBR® Green I. Intact, high molecular weight DNA migrates as a single large band at the top of a gel, whereas partially degraded DNA produces a long smear composed of large to small fragments (>20 000 bp to a few hundred base pairs for human DNA). DNA molecular weight ladders run alongside the sample lanes are used as reference size markers. For many PCR-based DNA typing assays, an evaluation of DNA degradation is not performed in order to conserve potentially limiting quantities of DNA. Rather, the extent of DNA degradation can be assessed indirectly by examining the outcome of the PCR amplification. Partial profiles as well as failure to produce a profile are often indicative of DNA degradation when the presence of an inhibitor has been discounted.

Quantification of the amount of DNA present in the extract is required to optimize the DNA typing assay, particularly if the latter involves PCR amplification. Knowing the initial quantity of DNA template can reduce undue consumption of biological specimen and reagents and can prevent the generation of potential PCR artifacts under suboptimal conditions. In general, two categories of procedures are available to estimate the quantity of DNA. The first category defines methods that are not specific to the human species. Such methods estimate the total amount of DNA in an extract. For example, the quantity of DNA can be estimated by measuring the absorbance of a DNA solution at a wavelength of 260 nm using a spectrophotometer. Using a quartz cell with a path length of 1 cm, a concentration of 50 μg DNA/mL yields an A_{260} of 1.0. The relative purity of the DNA sample can be assessed by including a measurement for the absorbance at 280 nm. By doing so, one searches for traces of phenol and residual amounts of aromatic amino acids signifying the presence of residual proteins. The investigator then derives an absorbance ratio for A_{260}/A_{280}. A ratio of 1.8 is usually indicative of a clean DNA preparation. Alternatively, yield gels can be used where the sample DNA and a series of DNA standards of known concentrations are compared by agarose gel electrophoresis and ethidium bromide or SYBR® Green I staining. Total DNA quantification can also be performed in the presence of the intercalating fluorescent reagent Picogreen® that binds primarily to double-stranded DNA. In a typical assay, samples of unknown quantities of DNA are compared to a series of serially diluted DNA standards after being mixed for

5 min at room temperature with the dye in 96-well assay plates. Light emission (fluorescence) measurements are then made using a fluorimeter. This method is particularly sensitive and can detect DNA down to 0.05 ng/μL.

For the quantification of human-specific DNA, an aliquot of the DNA sample is denatured (converted into single-stranded molecules) in alkali along with serial dilutions of DNA standards. Each sample is then adsorbed and covalently bound to a charge-modified nylon membrane. The immobilized DNAs are hybridized to a radiolabeled, chemiluminescent or colorimetric, primate-specific α-satellite DNA probe (p17H8) fragment that targets highly repetitive human DNA sequences located at the D17Z1 chromosome locus. This method is capable of detecting subnanogram amounts of human DNA. A recent approach eliminates the need for DNA immobilization on membranes and uses solution hybridization of DNA probes targeting highly repetitive human Alu DNA elements coupled to an enzyme-linked chemiluminescence reaction to estimate the quantity of human DNA in the sample.

Quantification from processed biological samples immobilized on FTA® filter paper is typically not carried out because a punched disc of uniform diameter (1.2 mm, 2 mm, or 3.7 mm) and depth contains a relatively consistent quantity of DNA bound to the matrix and produces equally reproducible amplification profiles for specific DNA VNTR targets.

1.3 Specimen Analysis

For many years, RFLP-based DNA typing was considered the standard method for most identification purposes. This method has since been replaced by PCR-based analytical strategies, particularly for human identification. RFLP analysis is still widely used in plant and animal studies. The RFLP method produces excellent, valid, reliable, and easily interpretable typing results (Fig. 2). Despite these advantages, RFLP analysis has limitations. For instance, each analysis requires a minimum of 10 to 50 ng of high-molecular weight genomic DNA to permit hybridization to each probe used to reveal the banding patterns. The RFLP procedure is also time-consuming and labor intensive, often taking weeks to complete when full analysis requires multiple rounds of hybridizations to several probes to build a discriminating allele profile (i.e. a genotype).

To circumvent these limitations, AmpFLP and STR-based methods were initially developed to complement RFLP typing in humans. Both strategies focus on short VNTR regions (8 to 70 bp for AmpFLPs and 2 to 7 bp for STRs) that are amenable to amplification by PCR. Amplicons produced are typically 150 to 1500 bp and 100 to 500 bp for AmpFLPs and STRs respectively. It should be noted, however, that most loci targeted for PCR analysis are much less polymorphic than the hypervariable regions used for RFLP testing. STR markers, in general, have far fewer repeats than AmpFLP markers and offer less variation at any one locus, but, despite this characteristic, the power of STRs lies in the ability to combine them into a single amplification assay (i.e. a multiplex PCR reaction). Multiplex STR analysis, therefore, represents a major advance in DNA typing by providing enhanced power of discrimination and automation capabilities. In a typical scenario, paired sets of specific oligonucleotide primers flanking short polymorphic VNTR regions

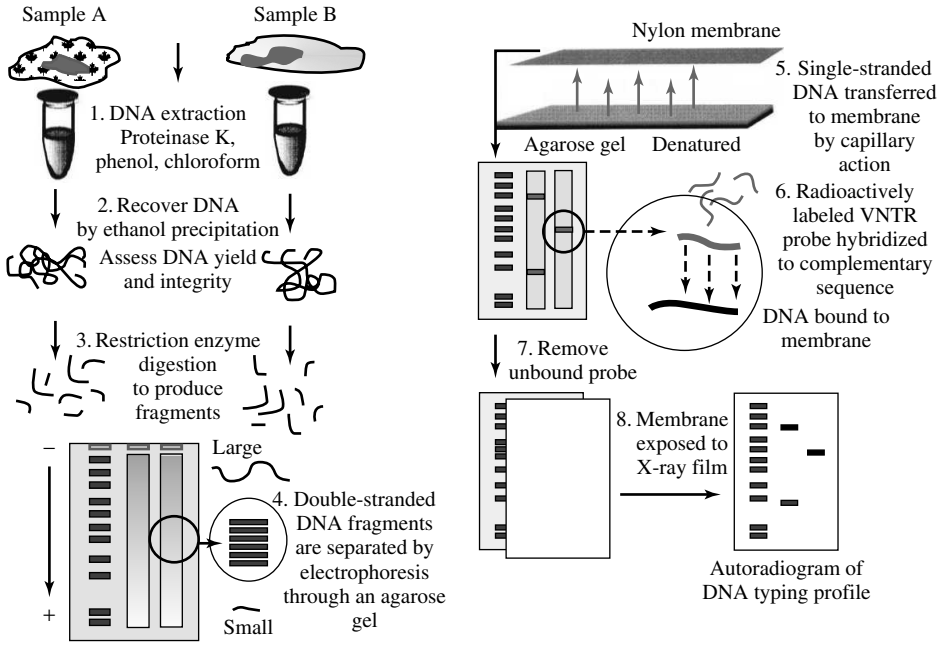

Fig. 2 Restriction fragment length polymorphism–based DNA typing process. Genomic DNA is first released from a biological sample by whole-cell lysis using a proteolytic enzyme (proteinase K) in the presence of a detergent (sodium dodecyl sulfate). Denatured proteins, peptides, and lipids are then removed by one or more organic extractions with a mixture of buffered phenol and chloroform. Genomic DNA is finally recovered by ethanol precipitation and both the yield and integrity of the DNA are assessed. The DNA is then cleaved with a robust site-specific restriction endonuclease (*Hae*III) to generate a series of DNA fragments of different lengths. These resulting fragments are resolved according to their sizes (lengths) by electrophoresis through an agarose gel. The negatively charged DNA fragments migrate through the agarose sieve toward the positive electrode located at the bottom of the electrophoresis unit. Once resolved, the series of DNA fragments is transferred by capillary action from the gel to a nylon membrane by a process known as *Southern blotting*. During this process, an alkaline transfer solution is used to unwind (denature) the DNA strands of each fragment and carry them along with the flow of transfer solution out of the gel and onto a charge-modified nylon membrane on which DNA strands will bind covalently. The membrane is then exposed to a radiolabeled or chemiluminescent complementary DNA probe that hybridizes with the membrane-bound denatured DNA fragments that contain target VNTR nucleotide sequences. Following a series of extensive washing steps to remove unbound probe, the membrane is placed in intimate contact with photographic X-ray film that is sensitive to the emission of β particles (decay products of the radioactive phosphorus atoms) or photons (generated by a subsequent light-emitting chemical reaction to detect hybridized probe). After an appropriate exposure time (minutes, hours, or days), the film is developed to produce a photographic image of the relative positions of the radiolabeled or chemiluminescent probe/target DNA hybrids on the membrane. The probes can be stripped off the membrane without removing the bound DNA, and the process can be repeated using a different probe that binds to a different set of DNA fragments. The composite data set of all DNA patterns generated using different probes is referred to as the *genetic profile* or *genotype* of the particular sample.

are used to amplify allelic DNA fragments that are then resolved according to their sizes by electrophoresis through polyacrylamide or other suitable synthetic polymer sieving matrices. The allelic DNA fragments are revealed using silver staining or fluorescence detection (Fig. 3).

A wide variety of biological samples have been successfully analyzed (genotyped) using the STR-based approach. In particular, allele profiles can be obtained from highly degraded DNA (in general about 100 bp in size) by simply redesigning PCR primer pairs to anneal closer to the STR sequence block. For a small percentage of biological samples from which only limiting amounts of highly degraded DNA are available, alternative typing methods, such as mtDNA analysis, have been developed and successfully applied.

Other types of nucleotide sequence polymorphisms can be detected in specific genes or noncoding regions of the genome by exploiting ''allele-specific oligonucleotide (ASO) hybridization'' probes. When these are used in a ''dot-blot'' format, the target DNA sequence is amplified by PCR and the amplification products are fixed to membranes. The DNA is then incubated with labeled ASOs, which hybridize only to DNA sequences that contain their exact complement. If hybridization occurs, the dot will be highlighted. If the amplified DNA does not correspond to the proper allele, the spot will remain blank. Alternatively, dot blots can be configured such that it is the

Fig. 3 Short tandem repeat–based DNA typing process. Genomic DNA is first released from a biological sample by whole-cell lysis using a proteolytic enzyme (proteinase K) in the presence of a detergent (sodium dodecyl sulfate). The DNA in solution is then recovered by ultrafiltration through specialized membrane units, or, alternatively, can be captured on magnetic beads to yield high-purity DNA ready for PCR amplification. Amplification is carried out in a thermocycler. During this process, multiple copies of STR-containing DNA regions are generated by a heat-stable DNA polymerase (i.e. *Taq* DNA polymerase) that uses sequence-specific oligonucleotide primer pairs that bind to complementary regions flanking the VNTR (shown in orange). The PCR process consists of three simple steps. In the first, the double-stranded DNA molecule is heat denatured (strands A and B unwind from each other at 95 °C). In the second, primers bind to their complementary sequences as the temperature is lowered (50 °C–65 °C), and in the third, daughter DNA strands are synthesized by the *Taq* DNA polymerase as the enzyme extends the hybrid DNA template–primer complex as the temperature is augmented to an optimum (72 °C). The first amplification cycle generates two copies of the original VNTR region. Repeated cycles of amplification generate millions of copies of the VNTR region according to a 2^n logarithmic rule where n represents the number of amplification cycles. Multiple primer sets labeled with different fluorochromes (denoted as FL in the diagram) can be used simultaneously (''multiplex PCR'' approach) to amplify multiple VNTR regions from different chromosomal loci within the genome. The resulting colored fragments are resolved according to their individual sizes by polyacrylamide gel electrophoresis. The size fractionation and detection of the amplified fragments occur simultaneously in an analytical instrument called a *DNA sequencer*. During electrophoresis, the DNA fragments migrate toward the bottom of the gel and reach the detection window where an argon laser excites the fluorochrome attached to one of the 5′ ends of the amplified DNA fragments. The photons emitted are captured in real time by a charged-coupled device (CCD) camera housed in the instrument and calibrated to the emission spectra of the fluorochromes. A gel image of the position of each of the STR-containing DNA fragments is then produced against a reference allelic ladder. The allelic ladder represents a composite migration set of the many STR-containing fragments detected in the general population. The composite array of all STR signatures amplified for a given sample is referred to as the *genetic profile* of that sample. (See color plate p. xxxii.)

ASOs that are fixed to the membrane, and the amplified DNA is allowed to hybridize to the immobilized probe sequences. This ''reverse dot-blot'' approach is routinely used for HLA-DQα typing, ''polymarker'' profiling and mtDNA typing.

Nucleotide sequence polymorphisms can also be detected in plants and animals using a scheme for generating ''randomly amplified polymorphic DNA'' (RAPD) segments. The ensuing methods are known as *arbitrary primed polymerase chain reaction* (AP-PCR) or *DNA amplification fingerprinting* (DAF). AP-PCR and DAF typing systems rely on PCR primers of arbitrary sequence. The latter are allowed to anneal to the flanking regions of target DNA regions. Annealing must occur over reasonable distances in order to facilitate amplification. Each system differs according to (1) the length of the primers used, (2) amplification conditions, and (3) the way in which amplified products are resolved and detected. Amplification will not occur if the template sequence differs significantly from the primer sequence. The main advantage of RAPD methods is that nucleotide sequence information is not required to design primers for a particular genomic DNA. Nucleotide sequence information is paramount, by contrast, for successful design and application of AmpFLP and STR-based typing strategies.

ISSR-PCR typing provides yet another alternative method to derive highly reproducible allele profiles without knowing anything about the nucleotide sequence of an organism's genome. ISSR-PCR is particularly useful in plant and nonhuman animal DNA typing exercises. The assay is somewhat more specific than the RAPD approach since higher annealing temperatures (usually in the vicinity of 50 °C) and longer primers are used. ISSR-generated profiles are usually preferred over those obtained from RFLP and RAPD strategies because the great number of signature amplification products produced per primer (typically more than 200 bands) facilitates identification across many species. ISSR-PCR is not used for human identification because locus-specific assays are available.

The genetic profiles (genotypes) generated by each of the aforementioned DNA typing methods can be visualized and/or scored with the help of colored dyes, fluorochromes or fluorescent dyes, radioisotopes, chemiluminescence detection, or staining with silver-based compounds. Today, the vast majority of DNA typing exercises rely on chemiluminescence and fluorescence as sensitive, less hazardous, and readily automated detection methods.

1.4 Data Processing

Genetic profiles can be represented as (1) colored, fluorescent, or photographic dots; (2) band patterns corresponding to the position of DNA fragments following electrophoretic separation; or (3) direct nucleotide sequence information (e.g. AATCGTACCTGATCC). While such data can be evaluated visually, computer-assisted analyses greatly facilitate allele resolution, detection, pattern interpretation, data storage, and statistical evaluation, particularly when data streams are abundant.

For dot-blot profiles, most comparative interpretations are performed by ''eye'' against known standards. The data are generally transcribed manually into a computer-managed database. However, since most dots are colored or visible on X-ray film, densitometric scanning systems can be used to automate the

scoring and storage of DNA profiles for subsequent analysis.

VNTR analysis relies on size and position as fundamental allele characteristics. The first generation of data acquisition systems used a simple ruler to determine the relative size of unknown DNA allele fragments by comparing their migrations with those of known DNA size standards on autoradiograms. In the early days of forensic human identification, semiautomated computer-assisted image-capture systems (which act essentially as electronic rulers) quickly replaced this rudimentary method of data analysis. This improvement reduced labor, tedium, and subjectivity and enhanced reproducibility. At present, fluorescence detection systems allow labeled DNA fragments to be detected, analyzed, and downloaded to databases in real time. The inclusion of internal size standards also allows PCR-amplified allelic signatures to be accurately and reliably scored, while sophisticated software packages assign each amplified DNA segment an allele designation number.

Analyses of nucleotide sequence polymorphisms, such as those applied to mtDNA, are typically carried out using commercial fluorescence-based nucleotide sequencing kits. Here again, specialized data collection and analysis software suites are required to expedite the reading and interpretation of DNA sequences.

High-throughput fluorescence analysis of SNP signatures is currently performed on DNA microarrays (a miniaturized high-density format of the dot-blot system). In this assay, which is now fully automated, a series of oligonucleotide DNA probes corresponding to individual SNPs are spotted as a two-dimensional high-density array on the surface of a glass slide. The arrays then serve as baits when hybridized to fluorescently labeled amplified DNA fragments. The presence of an SNP signature is revealed by matching the fluorescence signal to the coordinates of the oligonucleotide probe on the array. Data capture and interpretation is achieved using dedicated scanners and computer software. The principal advantages of automated sample processing and data-acquisition platforms are the reduction of time, labor, and human error in the transcription of data. Data files can be accessed and further studied to determine the statistical significance and linkage properties of one or more SNPs.

1.5 Quality Assurance and Quality Control

Quality control management is paramount to obtaining quality results. It is also a key factor in establishing uniform reliability of data and practices between laboratories. Laboratory quality assurance consists in verifying and documenting that all procedures relevant to DNA typing exercises have been performed by skilled, highly trained personnel. The validity of DNA typing data relies on correct identification of true ''nonmatches'' as well as true ''matches'' from prospective DNA typing profiles. The reliability of a test reflects its reproducibility under defined conditions and its ability to transcend different laboratories and practitioners. Quality assurance must encompass all significant aspects of the DNA typing process. These include personnel education and training, documentation of records, data analysis, quality control of reagents and equipment, technical controls, proficiency testing, reporting of results, and auditing of laboratory procedures. The principles and practices of quality assurance and the development of appropriate standards and guidelines for

DNA typing emerged initially from the experience of clinical laboratories. These have now been carefully defined through consensus between forensic laboratories represented in the North American Non-Regulatory Federal Initiative, the Scientific Working Group on DNA Analysis Methods (SWGDAM), the European DNA Profiling Group (EDNAP), and the European Network of Forensic Science Institutes (ENFSI). Recently, some laboratories performing forensic analyses have developed a quality assurance system on the basis of international standards such as the ISO/IEC 17025. It is important to note that quality assurance guidelines in forensic science must retain enough flexibility to accommodate the unique nature and diversity of forensic samples as well as future advances in recombinant DNA technology, molecular biology, genetics, and instrumentation.

Most laboratories engaged in DNA typing analyses seek accreditation. Accreditation represents the formal recognition of the competence and quality of the laboratory and secures international recognition that the quality of the work performed meets exacting standards.

2 Applications

2.1 Criminal and Forensic Investigation

2.1.1 Human Identity

Violent crimes such as sexual assault or murder are often associated with multiple acts of aggression and defense that lead to the transfer of DNA-containing material between assailant and victim. Tissue, blood, or other biological material recovered from the crime scene, therefore, provide a source of forensic evidence that can help determine the circumstances of the event as well as the provenance of the specimens (Fig. 4). Accident or homicide victims, unidentifiable from their physical features, can be identified provided ''typeable'' DNA can be isolated from the victim's remains and matched with the allele profile generated from DNA extracted from, for example, hair roots or scalp cells collected from his or her hairbrush. If the victim's parents or other blood relatives are available, parentage testing may also be performed (Fig. 5). Genetic relatedness diminishes over generations. Biological parents provide a direct genetic link to the victim, whereas maternal or paternal aunts or grandparents share fewer alleles with the victim. Sisters and brothers of the victim can be either very informative or noninformative depending on which alleles are inherited by each member of the family. Genetic relatedness across multiple alleles can generally provide a combined DNA profile that allows the likelihood of relatedness to be determined. In essence, the more DNA tests performed or the closer the relatedness of potential blood relatives, the higher the probability of determining identity. In cases where nuclear genomic DNA may be lacking or unusable, mtDNA or loci from the nonrecombinogenic section of the male Y chromosome can be exploited to identify and link family members.

Reference samples often collected from victims, their parents, or other close relatives include whole blood and buccal swabs. Archival pathology specimens (such as paraffin-embedded tissue or histological sections mounted on glass slides), despite their small size and degree of processing, can serve as adequate resource material for the identification of individuals.

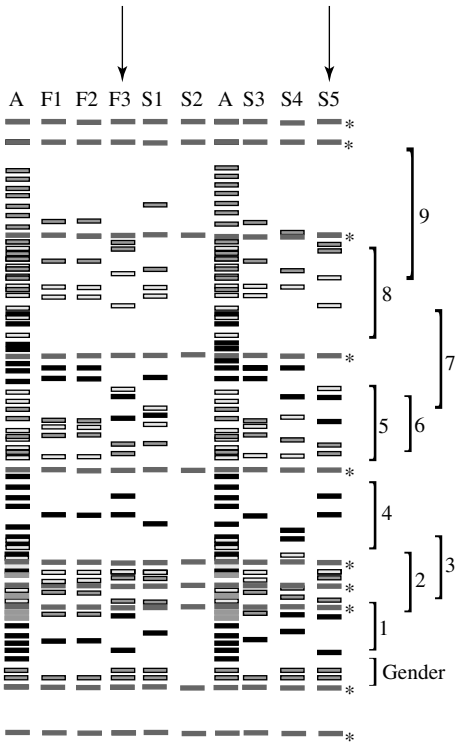

Fig. 4 STR analysis of a sexual assault case. In sexual assault cases, evidence samples such as oral, vaginal, and anal swabs are routinely collected and submitted for DNA typing analysis. Often, swabs present as a mixture of the assailant's sperm and the victim's epithelial cells. Both cell types can be separated from one another using a ''preferential lysis'' procedure that eventually releases crude genomic DNA from the epithelial cells in the first ''wash'' and second fractions (referred to as fractions F1 and F2 respectively), and crude genomic DNA from sperm cells in fraction F3. Each fraction is then subjected to sequential rounds of phenol/chloroform extractions to yield high-purity DNA that can then be used for PCR amplification using nine sets of STR primer pairs in a ''multiplex'' analysis. To facilitate real-time detection and sizing during electrophoresis on the DNA sequencing instrument, each set of allelic DNA fragments is labeled with its own fluorochrome ''tag'' during PCR amplification. Gel images are produced by the instrument and downloaded to a computer workstation where the analyst scrutinizes the data and interprets the allele profiles using specialized software suites. Individual STR allele signatures are scored against an internal DNA standard (marked with asterisks). The latter is a collection of red fluorescently tagged DNA fragments of known sizes that are included with each ''run'' sample on the gel in order to correct for minor variations in electrophoretic migration. The internal standard is also used to generate a calibration curve to estimate the size of each STR fragment. The allelic ladder (denoted as A in the diagram) is a composite of the alleles most frequently encountered for each of the nine STR loci surveyed in individuals sampled at random in the general population. Each band in the ladder has been sequenced so that the exact number of tandem repeats displayed in these fragments is known. The ladder is used to determine the number of tandem repeats present in each of the amplified fragments generated from biological samples. Appropriate positive and negative controls are always incorporated to verify the efficiency and accuracy of the extraction and amplification processes (referred to as S1 and S2 respectively, in the diagram). Because no amplified products are detected in lane S2, one can assert that the components used in the amplification reaction were not contaminated with any external source of DNA. As a rule, in processing a criminal case for DNA analysis, the evidentiary lanes on a gel are separated into ''questioned'' and ''known'' samples. The ''knowns'' usually correspond to DNA from fresh blood samples taken from victims (referred to here as S3) and suspects (referred to here as S4 and S5 for suspects 1 and 2 respectively). These ''knowns'' are compared to the ''questioned'' samples obtained from crime scenes, which, in this case, were vaginal swabs from the victim. Visual inspection and statistical analysis of the electrophoregram reveal matches between the F3 sperm cell fraction and the known sample from suspect 2 (S5) for all nine STR DNA regions examined. This is, therefore, a case of ''inclusion'' for suspect 2 (S5). Suspect 1 (S4), on the other hand, is ''excluded'' from being the perpetrator of this criminal offense. Statistical analyses are conducted to calculate the probability of a random match, that is, to estimate the odds of finding, by random chance alone, an unrelated individual, other than suspect 2, who would also produce matches on all nine DNA regions examined.

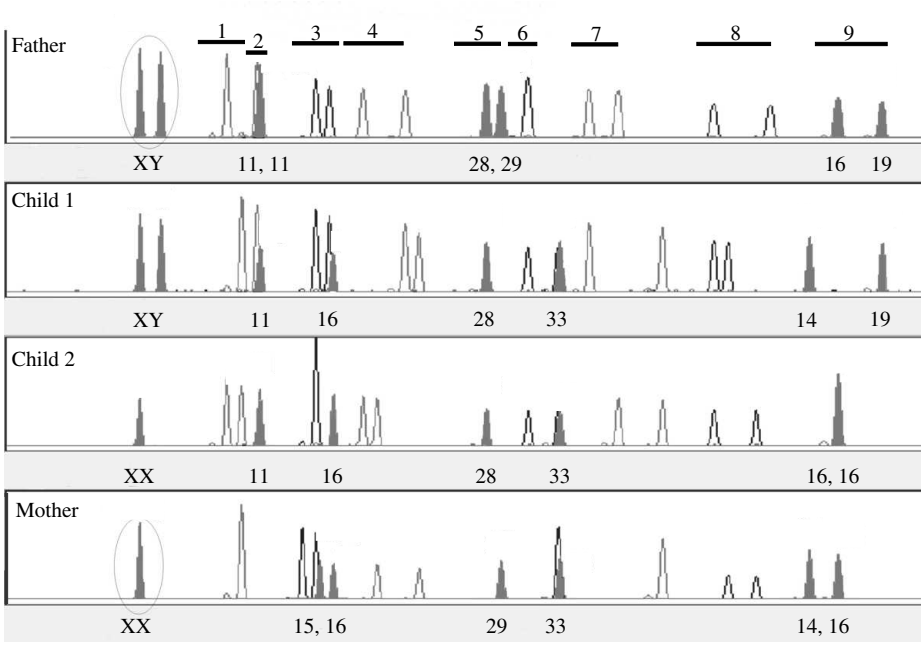

Fig. 5 Paternity analysis using short tandem repeats. Genetic profiles generated from blood samples or buccal swabs are shown for a typical family. Profiles are represented by a series of peaks that correspond to the sets of STR-containing allelic DNA fragments that migrated through a polyacrylamide gel in the DNA sequencing unit. The shorter STR fragments appear on the left side of the panel as they are the first to pass in front of the detection window of the instrument. The larger STR fragments appear on the right side of the tracing because their large size has delayed their migration and appearance in front of the detection window. In this particular example, nine STR loci (denoted as 1–9 on the diagram) have been amplified simultaneously in a ''multiplex'' PCR reaction. The test also includes an amplification reaction that provides an indication of the sex of the person from whom the sample originated. The presence of two peaks indicates a male signature (X,Y), whereas the presence of only one peak indicates a female (X,X) genotype. Since half of the genome of an individual is contributed from the mother and the other half is provided by the father, each of the nine STR loci examined has two potential signature (allelic) components (two peaks), one inherited from each parent. This provides a total of 18 points of comparison, which makes the test highly discriminating. It is therefore possible to identify which half of the children's DNA was contributed by which parent. In this particular example, child 1 has inherited allele 11 from his father and allele 16 from his mother for the STR region referred to as 2. For STR region 5, child 1 has inherited allele 28 from his father and allele 33 from his mother. For STR region 9, child 1 has inherited allele 14 from his mother and allele 19 from his father. Brothers and sisters (siblings) are likely to share one or more allele signatures as similar alleles may have been inherited from the mother or the father. This is in fact the case for the children of this family who have inherited the same alleles from their parents for STR regions 2 and 5. Conversely, siblings may not share any alleles. This is demonstrated for STR region 9 where child 1 has inherited allele 14 from his mother and allele 19 from his father and child 2 has inherited the other alleles from his mother and father, that is, alleles 16 and 16. Parentage tests such as this one have been an invaluable resource for establishing kinship and identity in the wake of the Swissair and World Trade Center tragedies.

With the evolution of analytical methods, the role of DNA profiling in mass disasters has become increasingly important as demonstrated in the wake of the TWA 800 and Swissair 111 plane crashes and terrorist attacks on the World Trade Center. In each of these cases, allele profiling enabled the identification of human remains where all other methods had failed. Incidents such as these have brought DNA profiling to the forefront of public awareness.

DNA methods have also facilitated the identification of casualties of war and other armed conflicts. Confidence in this approach is such that the military in some countries now request soldiers to provide a biological sample for the derivation of a reference DNA profile, should the need for a match comparison arise in the future.

DNA analysis has provided assistance in some unusual circumstances where forensic evidence was originally thought not to exist. Investigators have found that insects that had fed on blood from a victim could be used to recover the human DNA evidence that eventually led to the resolution of the case. Analysis of hematophagous arthropod (i.e. biting insects) blood meals and excreta may indeed be rare, but such examinations can prove instrumental in identifying the assailant or excluding one or more potential suspects from the scenes of violent crimes (e.g. rape, homicide, child abuse).

The automation of the STR-based DNA typing process for biological samples collected on FTA® paper, paper strips, or cotton swabs has played an important role in allowing the construction of databases containing the DNA profiles of criminals convicted of designated violent crimes, such as sexual assault, homicide, and armed robbery, around the world. The use of simple commercial collection kits allows biological samples to be collected safely and without risk of cross-contamination. In countries where criminal DNA databases have been implemented, DNA profiles from convicted offenders are compared to the DNA profiles generated from biological samples collected from crime scenes. A DNA data bank can link a convicted offender's allele profile to more than one crime scene (which suggests a serial offender) and can link known offenders to crime scenes where the perpetrator was unknown. Data banks such as these have proven extremely useful in assisting law enforcement agencies to build cases against suspected offenders, to focus investigations, to protect the public, and to exonerate those falsely accused. International law enforcement agencies and the justice community in general are, therefore, experiencing first hand the benefits of DNA profiling. The success of a database is directly related to the number of samples registered. When more samples are loaded into the data bank, there is a better chance of generating a match to crime-scene evidence or to offenders who have already been convicted. As new DNA typing technologies are developed, measures will have to be put in place to ensure that existing databases are not rendered obsolete.

2.1.2 Animal Identity

There are numerous examples in the forensic record where cases were resolved by pivotal DNA evidence derived from nonhuman biological samples. Common examples include confirming or excluding an animal as being the cause of a traffic accident associated with high material damage and personal injury. Dog hair left as evidence at the site of a motorcycle accident, for example, can be used to

incriminate the animal and establish the cause of an otherwise unsolvable accident. In addition, saliva from canine bite wounds on a deceased individual can be used to trace the animal responsible for a fatal attack.

Poaching of animals on the endangered species list is a criminal offense. Species identification as well as authentication of various processed biological materials can be achieved using DNA methods. A dried processed skin suspected to be that of a poached tiger was certified as an imitation derived from cattle skin painted to look like tiger skin. A similar approach was used to demonstrate that trace evidence recovered from the remains of an animal found at an illegal poaching site in a national park matched that of the confiscated frozen meat.

The protection of endangered animal species requires inexpensive, accurate, reliable, rapid, and easily adaptable strategies like those offered by PCR-based DNA analysis techniques to verify identity. Protein-based identification techniques become less reliable with heat-treated products, such as canned or smoked fish. Processed seafood products (like caviar and other meat preparations) often contain material from several species even though regulations stipulate that the contents of a container should be unique. Laws also require that products be labeled with official names to discourage fraud. The use of genotyping methods to determine the authenticity of samples can assist international conservation and legal agencies to better manage and preserve commercial species populations while protecting species at risk. PCR-based methods give wholesalers alternatives to crude identification methods and, more importantly, protect consumer groups against paying exorbitant prices for mislabeled food products.

2.1.3 Plant Identity

DNA typing analysis has been useful in the identification of regulated or prohibited plant material, such as Cannabis (marijuana). PCR-based methods are so sensitive that they allow detection of the presence of *Cannabis sativa* DNA on the skin of persons who recently handled both leaf and resinous material.

The traditional method of detecting the fraudulent propagation of ornamental cultivars required much time and effort, principally because it was based on the phenotypic analysis of plants grown to the flowering stage. This laborious approach is rapidly being superseded through implementation of databases of reference cultivar DNA profiles. By way of example, the rose is one of the most economically important landscape or cut-flower ornamental species in the world. In France, efforts are being deployed to derive reference genotypes for the more than 1500 rose varieties maintained in the French reference collection by PCR-based methods. PCR-based assays have also assisted in solving cases of unauthorized sale of spurious chili seeds raised by an individual and marketed under the brand name of an elite variety. In the same vein, standard-quality rice has been sold as the premium-priced basmati rice. Similar typing methods were successfully applied to expose the fraud.

VNTR markers have also proven effective for genotyping individual trees in forest crime prosecutions. Illegal tree harvesting destroys habitat and reduces diversity within parkland and protected ecological sectors. Theft of standing timber continues to represent a growing problem in the western part of Canada where red

cedar (*Thuja plicata*) is particularly targeted by thieves because of its high commercial value. Forensic experts are now using microsatellite markers to match illegally harvested tree stumps to suspected stolen wood. In addition, chloroplast DNA analysis allows discrimination of species from dry wood samples. On a more sombre note, the RAPD technique has been successfully used to link seedpods recovered from the truck of a suspect's car to the paloverde tree under which a murder victim had been buried.

2.1.4 Fungal Identity

Several truffle species are among the most valuable mushrooms on the market because of their aroma and culinary qualities. They represent a valuable source of agricultural income in some areas of southern Europe. DNA profiling allows rapid control of production quality and identification of truffle fruit bodies in fresh or canned preparations. The recent occurrence of Asian truffles morphologically similar to *Tuber melanosporum* on the European market raises two kinds of problems – one is fraud, because Asian truffles are cheaper and of lower quality, the other is ecological in nature, because Asian black truffles may be used (knowingly or not) as inoculum for the production of seedlings destined to be planted in Europe.

2.1.5 Bacterial Identity

Forensic investigations often require that the presence of ethanol in postmortem blood and tissue samples be determined. However, it is well documented that a variety of microbes can produce significant amounts of ethanol under postmortem conditions. DNA analysis allows investigators to identify the microbial species present in tissues, blood, urine, and other body fluid samples from victims in order to help determine if the cause of a fatal motor vehicle or airplane accident was indeed attributed to the consumption of alcoholic beverages. In such cases, sets of PCR primers are usually designed to hybridize to the 16S ribosomal RNA genes in order to help identify microbial species. More recently, VNTR and STR typing were employed to identify the strain of anthrax delivered through mail by terrorists in New York, Washington DC, and Florida.

2.1.6 Viral Identity

When sexual assault results in HIV transmission, a criminal charge of conduct endangering life, in addition to rape, may become an option for the prosecution if the carrier was aware of his infection status. In such a case, direct sequencing of the viral genome is used to demonstrate that the strain infecting the perpetrator matches that of the victim. Other cases of criminal viral transmission that have been resolved by DNA analysis include those of a dentist with AIDS who infected several clients and HIV-infected surgeons who transmitted the virus to their patients.

2.2 Clinical Medicine

The ability to discern whether a specimen originates from a particular source is often critical to diagnosis, to laboratory analysis, and to exercises where the endpoint is quality assurance. For example, because the results of a positive drug test could have significant economic and social consequences, the number of submissions of adulterated or substituted urine specimens has increased. DNA analysis acts as a safeguard by allowing confirmation that the urine that tested positive for the drug of abuse was in fact provided by the donor.

DNA analysis in the clinical laboratory is paramount to ascertain the provenance of tissue biopsy specimens (i.e. normal vs malignant tissue) and blood specimens where either could be mislabeled at the time of collection. Under such circumstances, accurate specimen identification prevents misdiagnosis and unnecessary treatment. VNTR-based methods have recently been used to demonstrate that a malignant melanoma that had suddenly arisen in a kidney transplant recipient had in fact originated from the tissue of the donor.

Other applications in medicine include genetic counseling, tracing the percentage of donor versus recipient cells in bone marrow transplants, determination of possible ''contamination'' of fetal chorionic villi sample (CVS) tissue with maternal tissue, and the confirmation of twin zygosity.

The application of STR genotype analysis to demonstrate the occurrence of needle sharing provides an excellent tool to evaluate the safety of the needle-exchange program as an adjunct to attempts at reducing the risk of HIV transmission in intravenous drug users. Since common injection practices leave sufficient quantities of trace DNA that can be efficiently amplified by PCR, investigators can easily profile the history of use for each syringe.

DNA profiling offers rapid and accurate identity testing in human and other animal cell lines registered in large repositories. This is particularly important because a significant fraction of research results could be misinterpreted if the cell lines used turn out not to be of the specified origin. Cross-contamination of cell lines continues to plague repositories and constitutes an unacceptably frequent cause of data correction or retraction. DNA methods allow comparison of parental and derived cell lines and ensure their authenticity.

The ability to identify the victims of blood-sucking insects is valuable to medical and forensic entomology. Studying variations in the biting rates and insect preference for different people could have important consequences for the epidemiology of vector-borne diseases. Detailed knowledge about the patterns of the mosquito's feeding behavior are used to develop improved disease control strategies by taking into account patterns of potential vector spread within and between communities and by concentrating intervention strategies on those individuals most at risk of sustaining bites and contracting infectious diseases.

2.3 Parentage Studies

2.3.1 Human Testing

Parentage can be determined for child custody and immigration cases. This is easily established because the bands in the offspring's allele profile must, by definition, have been inherited from the biological parents. Barring the rare instance of mutations, the presence of bands not found in either parental profile is indicative of nonparentage. A dramatic demonstration of a parentage study using STR markers and mtDNA sequencing was the identification of the remains of the lost members of the Romanov family in Russia.

2.3.2 Testing of Nonhuman Animal Species

Paternity testing has become an important tool for breeders of dogs, sheep, horses, and cattle. Biological relationships can be confirmed in artificial insemination and embryo transfer programs for

domesticated animals. DNA profiling is also used in breeding programs for populations of endangered species with small gene pools. Animals exhibiting the greatest number of DNA profile differences are taken as possessing the greatest degree of genetic diversity and are therefore selected for breeding. DNA profiling has also proven effective in identification of stolen or lost animals as well as in the establishment of relevant breeding (trait) markers. Recently, a set of bovine SNPs has been developed and is expected to facilitate the high-throughput genotyping of prize animals. High-resolution genetic markers such as microsatellites can provide detailed information about the mating habits of animal species such as alligators, turtles, chimpanzees, and Gypsy moths. Such analyses can reveal the reproductive dynamics of local populations and can provide much needed insight on population genetics and ecology.

2.4 Molecular Evolution

2.4.1 Evolution of Human and Other Animal Species

DNA typing analysis has revolutionized the study of human evolution. Numerous population studies examining VNTRs and nucleotide sequence polymorphisms have formed the basis of exciting new theories about human origins, diversity, and cultural expansions from the distribution and frequency of genes and genetic markers found around the world today.

Many museums routinely archive animal tissue for molecular, systematic, and taxonomic studies. The vast majority of museum specimens predates the advent of molecular techniques and consists of dried skins, skeletons, and formalin-fixed or ethanol-preserved material. The success of DNA recovery depends largely on the condition of the specimen. Small bones, only a few millimeters in length are a surprisingly excellent source of relatively intact DNA. Such material increases the value of museum specimens to systematic biologists. In fact, one of the first animal DNA analyses performed using PCR consisted in typing a museum skin specimen of the now extinct quagga.

The evolution of populations can be traced, for example, by analyzing DNA from well-preserved (i.e. dried) museum specimens or from insects naturally embedded in amber for millions of years. Base-pair sequences and allele-profile bands can be compared with those of modern relatives. PCR-based markers are being used extensively for reconstructing the phylogenies of various species. Such analyses provide much needed information regarding the fine timescale over which closely related species have diverged and about what sorts of genetic variations are associated with the emergence of species.

2.4.2 Evolution of Plants

Microsatellite markers have proven to be extremely valuable in the analysis of gene pool variations of crops during the process of cultivar development and in the classification of their germplasm. It is extremely important to study the genetic composition of the germplasm of existing modern-day cultivars and to compare the data with those of their ancestors and related species because studies such as these provide insight on speciation and divergence patterns.

Plant improvement, either by natural selection or through the efforts of breeders, has always relied upon creating,

evaluating, and selecting the right combination of alleles. Microsatellite markers are efficiently employed for ''tagging'' several traits (like yield, disease resistance, stress tolerance, and seed quality) that are beneficial to a breeding program.

3 Perspectives

3.1 DNA Typing versus Conventional Methods

The introduction of genetic methods to the field of human identification has all but replaced long-standing biochemical and serological techniques. The conventional methods of isoenzyme gel electrophoresis and blood antigen typing are admittedly rapid, simple, and definitive for exclusions, but they are much less powerful than DNA typing analysis for determining the probability of inclusion. If a mother and a presumptive father both share blood type O, their offspring cannot express the antigens for blood types A, B, or AB. Thus, the presumptive father is readily excluded as one of the biological parents in this example. However, if the offspring is of blood type O, exclusion of a man who is not the biological father but is also of blood type O (or heterozygous for the O allele) is considerably more difficult if the investigator relies solely on serological methods.

Additional key elements that have contributed to the adoption of DNA as the substrate for identity testing across every taxonomic kingdom include the ready availability of the hereditary material, the highly polymorphic nature of genomes, the continuity of the genetic script within each cell of an organism, the chemical stability of DNA relative to that of enzymes and other proteins, and the technical ability to amplify DNA regions in the laboratory when only a minimal amount of biological material, even partially degraded, is available.

DNA evidence is a matter of probabilities. In the absence of mutation, when two samples do not share similar DNA allele profiles, one can state with confidence that neither could have originated from the same individual. In this regard, the genetic evidence leading to the exclusion of a suspect sample is absolute. If two samples share the same genotype, the question now becomes, ''What is the significance of the match?'' If a sufficient number of polymorphic DNA markers are analyzed, then the power of discrimination becomes very high and the statistical probability of a random match becomes extremely low.

3.2 Future Directions

DNA typing technologies have consistently evolved over the past fifteen years. The trend is expected to continue and will probably be fueled by the various genome characterization and sequencing initiatives currently under way around the globe. The quest to unravel the secrets that lie within the genetic scripts of living organisms will no doubt lead to the discovery of novel polymorphisms and the development of selected sets of SNPs with exquisite powers of discrimination. Significant efforts are already being deployed toward the development of more efficient, effective platforms and analytical instrument systems to facilitate high-throughput surveys of SNPs and other elements of genetic variation. Prime examples of recent advances leading to the wider acceptance of SNP-based identification strategies include automation and the

design of prototype ''lab-on-a-chip'' microanalytical devices capable of performing cell separations, ultrarapid PCR amplification, liquid stream electrophoresis, resolution of DNA fragments, DNA sequencing, real-time data capture, and downstream processing. Parallel innovations in microarray design and high-density spotting are also anticipated to enhance our ability to expose genetic variation between individuals as a matter of routine practice both in centralized analytical facilities and in the field. With respect to the necessity of being able to work with limiting amounts of biological material, refinement of whole genome amplification strategies remains a priority so that forensic scientists may one day perform DNA analyses on samples containing a single genome equivalent. Equally important for single-cell or microanalysis will be the development of reiterative processes that will allow typing runs to be repeated many times on the same sample in order to sustain accuracy, reproducibility, and statistical significance. Whatever future developments hold in store, collectively, all of them will converge on ensuring that DNA typing processes can be performed at low cost to the end user with greater speed and greater efficiency without compromising accuracy or profile quality.

Keywords

Corepressor (Inducer)
A small coeffector molecule whose presence increases (decreases) the affinity of a repressor for its operator site.

Direct Readout
A situation in which amino acid side chains of the repressor protein make direct contacts with the edges of DNA base pairs to detect their sequence.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.
Copyright © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.
ISBN: 3-527-30545-9

DNA-binding Motif
A protein structural element primarily responsible for making sequence-specific contacts with DNA (e.g. the helix-turn-helix motif or the β-ribbon).

Indirect Readout
A situation in which repressor–operator complex formation involves sequence-dependent distortions to the DNA conformation.

Transcriptional control is the most important mechanism of differential gene expression in the vast majority of organisms. Repressors control transcription by binding to specific sequences (operator sites) in genomic DNA and sequestering those regions from RNA polymerase, hence preventing transcriptional initiation. Repressor–operator binding is controlled by the physiological state of the cell, either directly by changes in the active repressor concentration or indirectly by sensing of the levels of key metabolites. Operator binding is highly specific and is achieved by a large number of distinct molecular interactions. A combination of structural studies and molecular genetics has led to rapid recent progress in understanding this field. Repressor–operator interactions provide simple tools to regulate the expression of recombinant proteins in a variety of organisms such as bacteria and yeast.

1 Principles

1.1 The Operon Hypothesis

In the 1950s, geneticists realized that bacterial cells are able to regulate the expression of genes encoding enzymes controlling particular metabolic pathways depending on their physiological state. For instance, the enzymes enabling *Escherichia coli* to metabolize lactose are not constantly present in the cell, but their synthesis can be induced by the addition of lactose to the medium, the extent of induction being dependent on the levels of glucose, the preferred energy source (Fig. 1). To investigate the mechanism behind such enzyme induction, a series of elegant genetic experiments was performed by a group based in France, led by Jacques Monod, François Jacob, and their colleagues. Their results led to the formulation of the *operon hypothesis*, which has become the basic model for transcriptional control of gene expression. In general, regulated genes (or groups of genes) contain two sequence elements at their 5′ ends: a promoter, which defines the start sequence for the bacterial RNA polymerase, and an operator, which is the target sequence of a repressor protein. Binding of repressor to the operator interferes with either binding of the RNA polymerase, or its initiation of transcription, leading to repression of the enzymes encoded by the downstream genes (Fig. 2). The genes for enzymes involved in related processes, such as lactose utilization, may be clustered and regulated by a single promoter–operator site; that is, they

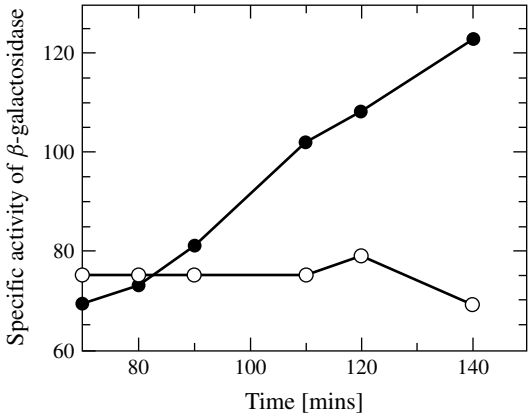

Fig. 1 Graph of the induction of β-galactosidase activity in bacterial cells in the presence (curve with solid points) and absence (open points) of the inducer, isopropylthiogalactoside (IPTG). The levels of induction of the other structural genes in the operon show identical behavior.

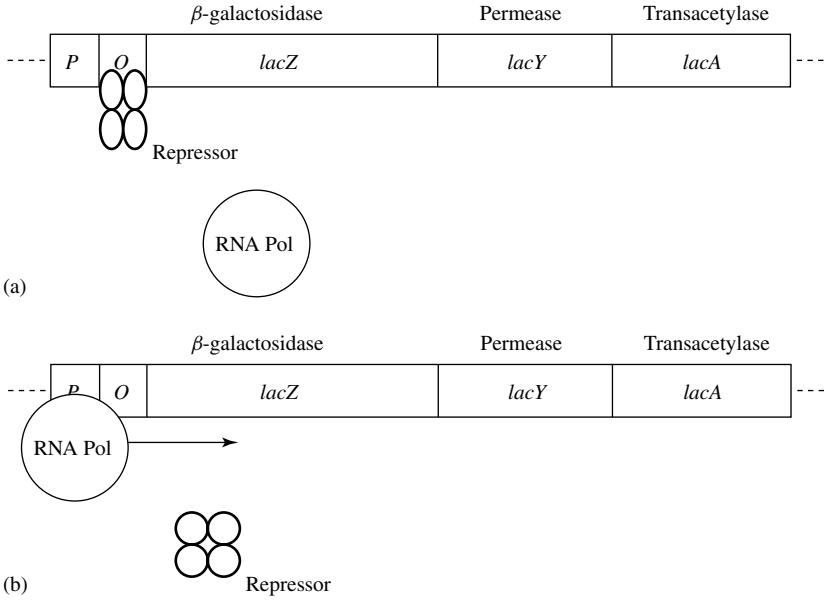

Fig. 2 Simplified diagram of the repression system in the *lac* operon. The DNA of the operon is shown on a block divided into three structural genes (coding for the enzymes required to metabolize lactose), the promoter site *P* where RNA polymerase (RNA Pol) binds, and the operator site *O*. Dotted lines indicate DNA flanking the operon. (a) The uninduced state in the absence of lactose (or allolactose). The repressor binds tightly to the operator, impeding access of RNA polymerase. (b) The induced state, where allolactose is present and binds to the repressor causing a change in its structure. As a result, the repressor can no longer bind to the operator, allowing RNA polymerase access to the promoter.

constitute an operon. It is also possible to have several separate promoter–operator sites regulated by the same repressor, a grouping that has been termed a *regulon*.

Repression often occurs in response to an environmental stimulus, such as the presence of the sugar lactose, by the binding of small coeffector molecules to the repressor proteins. Such coeffectors can increase or decrease the affinity of the repressor for its operator site; that is, they can act as either corepressors or inducers of gene expression. In the case of the *lac* operon, the presence of lactose in the growth medium leads to the production of a breakdown product, allolactose, which binds to the LacR repressor protein. This causes an allosteric conformational change in LacR, preventing the protein from binding to DNA. In the absence of allolactose, the repressor binds tightly to the *lac* operator, preventing transcription initiation by RNA polymerase. In the presence of allolactose, the repressor dissociates from the DNA, allowing transcription to begin, and mRNAs for the *lac* operon structural genes are produced. These encode enzymes for lactose metabolism such as lactose permease, which actively sequesters the available lactose into the cell and β-galactosidase, which breaks down the lactose into its component parts (Fig. 3).

In bacteriophage lambda, repression controls the switch between lytic and lysogenic growth, and this phage has

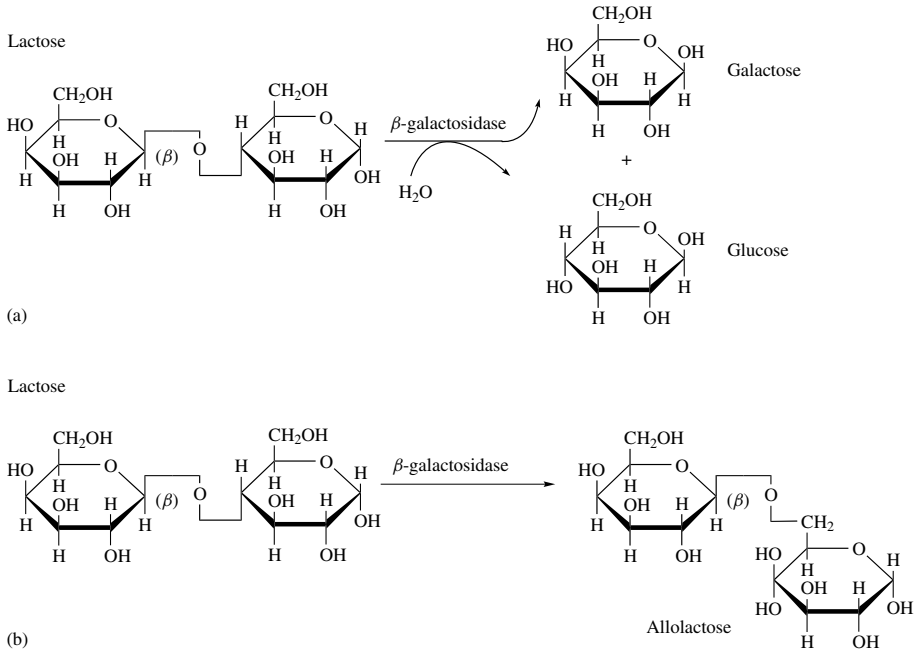

Fig. 3 The two reactions catalyzed by β-galactosidase. (a) Cleavage of the disaccharide lactose yields the hexoses galactose and glucose, which are both readily metabolized to provide energy for the cell. (b) The minor isomerization reaction produces allolactose, which acts as an inducer, binding to LacR and preventing it from binding to its operator site. Eventually, in the absence of lactose, the allolactose concentration falls, restoring the repressed state.

been one of the major model systems for studying the control of gene expression.

1.2 The Structures of Repressor Proteins

In the early 1980s, a number of three-dimensional structures of repressor proteins were determined by X-ray diffraction techniques. The first three proteins for which structures became available were phage lambda Cro, the *E. coli* cyclic AMP receptor protein (CRP), and lambda repressor (cI). Comparison of the polypeptide chain topology in these cases shows that although each protein has a unique overall fold, they all share a particular structural element, consisting of two α-helices linked by a rather unusual β-turn (Fig. 4). This helix-turn-helix (hth) motif is located on the surface of the protein in each case. All three proteins are symmetric dimers, and the two copies of the motif, one per subunit, are positioned such that the distance between them is approximately 34 Å. This is also the separation of the successive turns of the major groove of B-form DNA along one face of the DNA duplex. The observation immediately suggested that the hth was the DNA-binding site, a proposal subsequently confirmed by the so-called helix swap experiment, in which the amino acid residues exposed on the surfaces of the second helices from two phage repressors, 434 (λ) cI and P22 cI were swapped using site-specific mutagenesis. The resulting hybrid proteins acquired the operator binding properties of the newly inserted sequences; that is, the hybrid λcI protein bound to P22 operators and vice versa (Fig. 5). As a result of such experiments, the second helix of the hth motif became known as the recognition helix, implying that

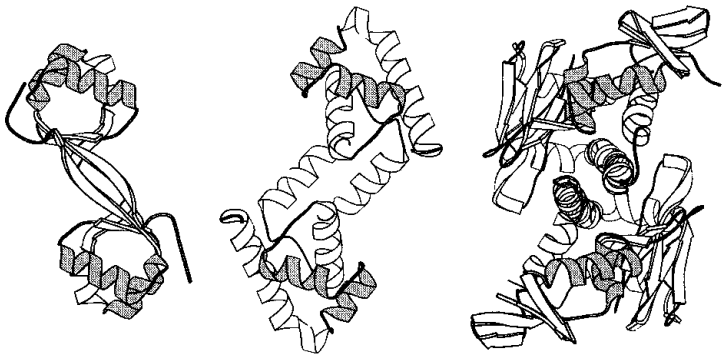

Fig. 4 Structural cartoons of three proteins, the bacteriophage lambda repressors Cro and cI repressors, and *E. coli* CRP, containing the conserved helix-turn-helix motif. (In the case of λcI, only the DNA-binding domain is shown.) Although the three structures are obviously quite different, pairs of hth motifs (shaded) are found in all of them, with a spacing corresponding to that of successive turns of the major groove of B-DNA. In each case, a DNA duplex bound to the protein would lie with its helical axis approximately vertical. In this and subsequent structural figures, coils represent α-helices and ribbons with arrowheads, β-strands. (Drawn with computer program MOLSCRIPT: Kraulis, P.J. (1991) *J. Appl. Crystallogr.* **24**, 946.)

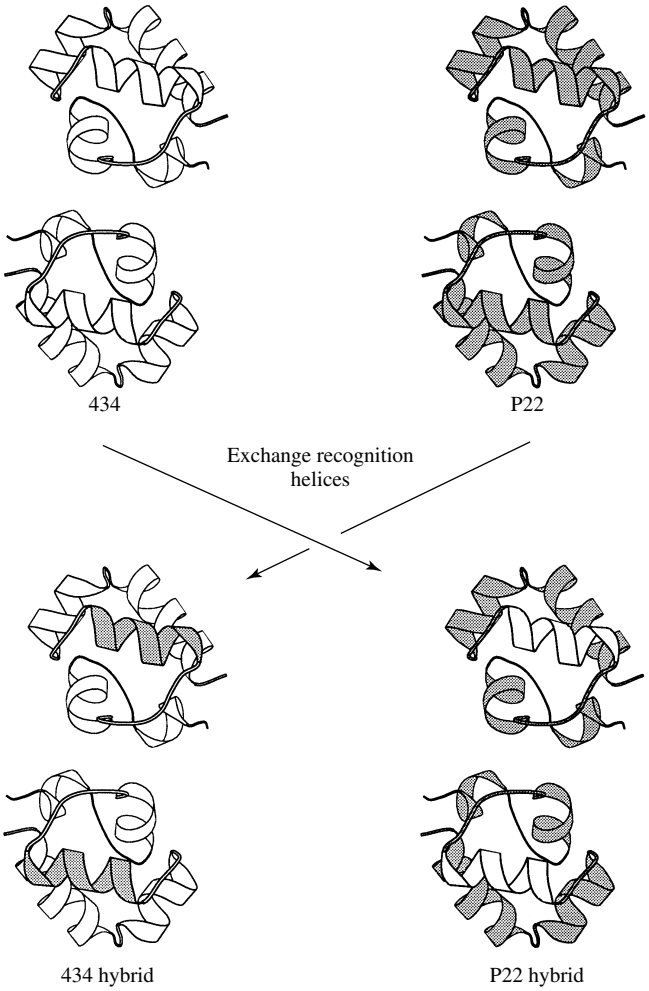

Fig. 5 The helix swap experiment. Recognition helices are exchanged between repressors 434 (open) and P22 (shaded), which have almost identical structures. After the swap, each repressor loses the ability to recognize its own operator, but will bind to that of the other repressor.

all operator recognition resided in it. As the three-dimensional structures of many more repressor–operator complexes have become available, this idea has proved to be an oversimplification (see Sect. 1.4).

The initial observation of a structural feature conserved between three repressor proteins was unexpected because there is very little amino acid sequence similarity between them. However, the structural studies allowed the identification of key residues within the hth motif (e.g. the presence of glycine in the turn). It was then possible to construct an algorithm to search the protein sequence database for potential matches with the hth motif.

The result was an impressive list of several hundred proteins, all believed to bind DNA, having the required sequence features of the hth motif. It is now clear that the hth motif defines a large family of proteins from both prokaryotic and eukaryotic cells sharing a conserved DNA-binding motif.

Although extremely common, the hth is not the only protein structural motif capable of binding to DNA in a sequence-specific fashion. Early model-building studies had suggested that both α-helices and antiparallel two-stranded β-ribbons have the structural features necessary to interact with duplex DNA. Two distinct families of proteins having β-ribbon DNA-binding motifs have now also been characterized. These are based on the *Bacillus stearothermophilus* HU protein, which is a nonsequence-specific DNA-binding protein, and the *E. coli* MetJ protein, the repressor of methionine biosynthesis. A number of other DNA-binding motifs have been identified in proteins regulating transcription in eukaryotic cells. It is likely that other families having novel DNA-binding motifs will be characterized in the near future.

1.3 Repressor–Operator Complexes

Operator sites generally contain palindromic sequences allowing dimeric repressor proteins to align with their twofold axes along the sequence dyad, thus generating two symmetrical sets of protein–DNA interactions. Repressors consisting of higher multimers such as LacR, which is a tetramer, or ArgR, the *E. coli* arginine repressor, which is a hexamer, nevertheless seem to be organized into pairs of subunits and retain the symmetry of the interaction with their operator sites. Figure 6 shows the structures of two repressors, one each from the hth and β-ribbon families. In both cases, the repressor–operator complex is formed by insertion of the DNA-binding motif into the major groove of the DNA duplex. A large number of specific intermolecular contacts are made between the DNA and the repressors, including hydrogen bonds and electrostatic interactions.

Both the TrpR (the *E. coli* tryptophan repressor) and MetJ repressors regulate the flux through biosynthetic pathways and must therefore alter the levels of repression at their various operons in response to the physiological state of the cell. This is achieved by the binding of two molecules of L-tryptophan to TrpR, and of *S*-adenosylmethionine (AdoMet), a derivative of L-methionine, to MetJ. The resultant repressor–corepressor complexes (holorepressors) have much higher affinities for operator DNA than the corresponding free repressors (aporepressors). However, the molecular mechanisms of these increases in affinity are quite distinct. In apoTrpR, the hth DNA-binding motifs are rather flexible and tend to lie too close together to fit easily into the adjoining major grooves of B-form DNA. Binding of L-tryptophan results in a concerted conformational change and general stiffening of the repressor dimer that stabilizes a structure in which the spacing of the hth motifs is more complementary to that of the DNA major groove (Fig. 7). MetJ, on the other hand, does not appear to alter its conformation significantly when it binds its corepressor. Indeed, AdoMet lies in a pocket on the opposite side of the molecule from the one that binds to DNA. In this case, it appears that the increase in affinity upon

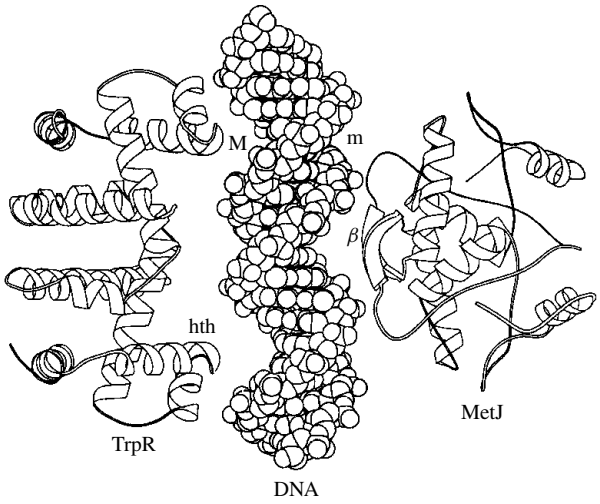

Fig. 6 Two turns of B-DNA flanked by structural representations of the active forms of left, the *E. coli* TrpR (tryptophan); right, MetJ (methionine) repressors. Both repressors are oriented correctly for DNA binding but have been pulled away slightly. As TrpR approaches the DNA, its two hth motifs can dock into adjacent turns of the major groove (M). As MetJ approaches, its β-ribbon (β) can dock into the central portion of the major groove. Corepressor molecules have been omitted for clarity.

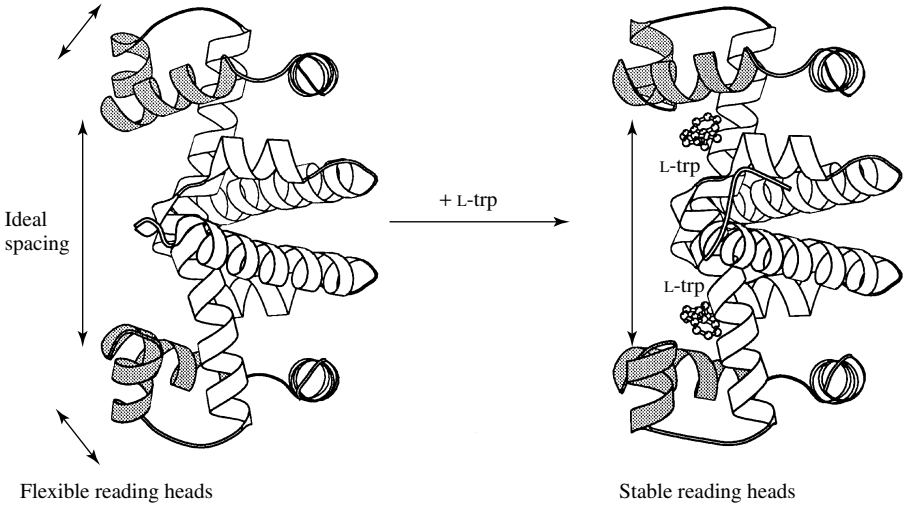

Fig. 7 Activation of TrpR repressor by L-tryptophan binding. In the absence of L-tryptophan, the hth reading heads are flexible and can collapse toward the middle of the repressor. When L-tryptophan is bound, the structure is stabilized, with the reading heads ideally spaced for DNA binding.

corepressor binding is due to a long-range electrostatic effect. Each AdoMet molecule carries a net positive charge, which helps to neutralize the negative charge on the DNA phosphate backbone, thus raising the affinity of the repressor for its operator. The differences in the molecular mechanisms of the corepressor effects in these two cases show that more than one mechanism has evolved to regulate repressor affinity for operator sites, and others may yet be discovered.

1.4 General Principles of Repressor–Operator Interactions

A bacterium such as *E. coli* has a double-stranded DNA genome consisting of more than four million base pairs, which at any one time will be partially replicated. Repressor proteins therefore must locate a few specific operator site(s) among a background of a large number of potential nonspecific sites elsewhere on the DNA. Indeed, since duplex DNA has a periodic structure, for any defined target size, translation along the DNA by just one base pair creates a new potential operator site. Target sites that occur once per genome are hidden among millions of nonspecific sites. To generate a target operator site that is unique in the genome, the repressor must be able to recognize a specific sequence of reasonable length. For instance, there is a 1 : 256 probability that a random 4 bp sequence will match a defined unique sequence by chance (i.e. there will be >10 000 such matches in the *E. coli* genome). However, the chances of a random match fall to roughly one in a million for sequences 10 bp long. Most operator sites characterized to date are between 12 to 20 bp in length and thus likely to be unique within bacterial genomic DNAs.

The sequence specificity of the repressor–operator interaction appears to be achieved in at least two distinct ways. The first relies on the fact that not all the functional groups on the bases are directly involved in Watson–Crick pairing, but are exposed in the major and minor grooves. Modeling studies suggested that individual base pairs could be recognized by formation of a series of hydrogen-bond contacts from amino acid side chains to these functional groups. Comparison of the two kinds of base pairs showed that discrimination would be more effective in the major groove because of the number and diversity of the contacts that could be made (Fig. 8). Such interactions have been observed experimentally in many repressor–operator complexes. This type of interaction has now been termed "direct readout," since the protein makes direct contacts with the edges of operator base pairs (Fig. 9). The modeling studies had suggested that bidentate side chains, such as glutamine and arginine, could make specific contacts to particular base pairs in 1 : 1 interactions, giving a simple protein-DNA recognition code. In the observed structures of repressor–operator complexes, however, there are more complex interactions in which side chains often contact more than one base pair. Thus, there is no simple code relating amino acid to base sequences. Rather, complexes contain a constellation of interacting side chains, main chain atoms, and nucleotide bases with many contacts contributing to the overall specificity.

A second type of interaction, termed "indirect readout," has also been identified: when complex formation involves sequence-dependent conformational distortion of DNA, increased intermolecular

complementarity (or interaction) results. An example of this type of interaction is shown in Fig. 10 for MetJ. The MetJ repressor is a dimer, and two of these bind to the minimum 16 bp operator site, which consists of two 8 bp sequence repeats (dA-GACGTCTAGACGTCT). Each repressor interacts, via direct readout, with the base

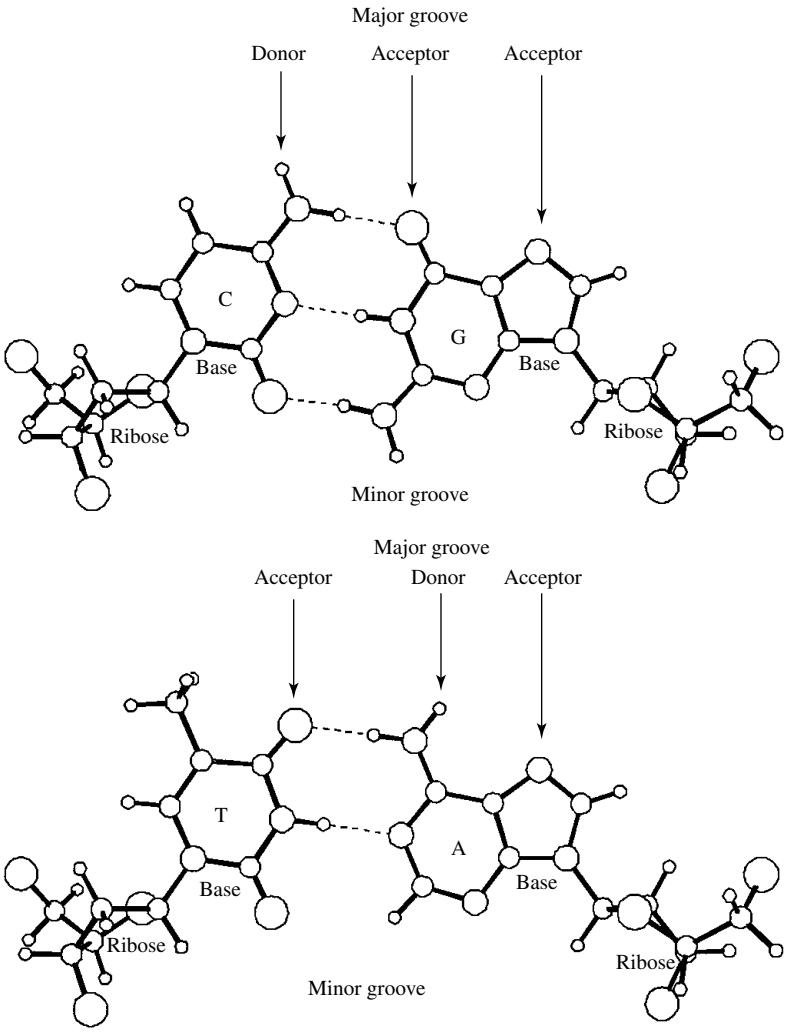

Fig. 8 The two possible kinds of base pair viewed along the DNA helix axis. The smallest circles represent hydrogen; the largest, oxygen; and the second largest, nitrogen atoms. The remaining circles represent carbon atoms. The upper edges of the bases are exposed in the major groove, and each has a unique pattern of hydrogen-bond donors and acceptors. Each base pair can be reversed, of course, leading to two further different patterns when exact positioning is taken into account. The sugar-phosphate backbone links adjacent base pairs through the outer edges of the riboses.

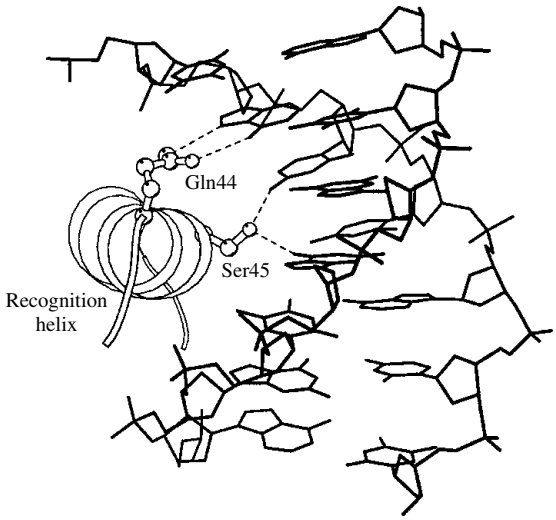

Fig. 9 The recognition helix of λcI repressor lying in the major groove of its operator. Of the 10 amino acid residues in the helix, the side chains are shown as balls and sticks only for the two that make direct hydrogen-bond contacts to the bases (dotted lines). Gln44 has a hydrogen-bond donor and acceptor, allowing it to make two bonds to the acceptor and donor present on the A base (see Fig. 8).

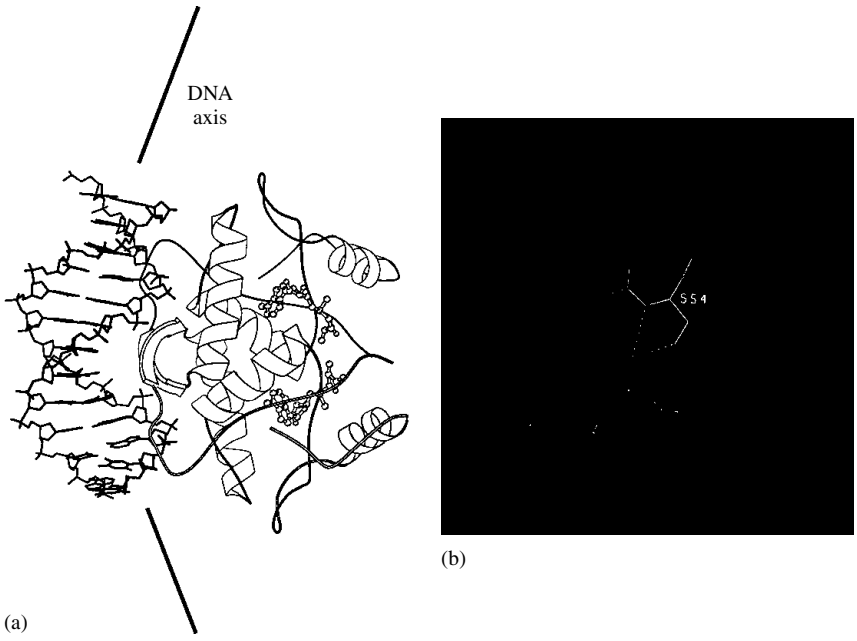

Fig. 10 (a) Bending of DNA when bound to MetJ repressor, allowing it to follow the protein surface more closely. (b) Close-up view of DNA distortion in the MetJ repressor–operator complex. One end of an α-helix in the repressor (blue) makes hydrogen-bond contacts (dotted lines) to a phosphate group in the operator (green). If the DNA were in the undistorted B-conformation (red), the phosphate would be out of range of this interaction. [Redrawn from *Nature*, **359**, 287–393 (1992).] (See color plate p. xxxv.)

pairs within each operator half-site. The half-site is bent toward the protein, wrapping snugly along its surface, thus increasing the structural complementarity of the components of the complex (Fig. 10(a)). However, the overall repressor–operator interaction is also sensitive to the sequence at the junction between the two half-sites, 5′-CT·AG-3′. The T.A base step at the junction is easily distorted away from the B-form conformation because of the relatively poor stacking energy of pyrimidine bases on purines, and especially T on A. In the MetJ–operator complex, this step is overwound, resulting in displacement of the phosphate 5′ to the T.A step from its expected B-DNA position by about 1.5 Å (Fig. 10(b): see color plate p. xxxv). The repressor can then make a number of hydrogen bonds to this phosphate, which it could not do with the phosphate in the standard B-DNA conformation.

The problem remains of how repressor proteins locate their specific operators in the presence of the large background of competing sequences against which they must discriminate. Essentially all sequence-specific DNA-binding proteins will also bind to noncognate DNA sequences, but with much lower affinity. Thus, in the cell, most repressors would be expected to be bound either specifically or nonspecifically to the genomic DNA molecule. The interactions in nonspecific complexes appear to be mostly electrostatic, the protein interacting primarily with the negatively charged phosphodiester backbone. Hydrogen bonds to base pair edges may occasionally also be made, together with contacts owing to DNA conformational distortion. Only at the true operator site, however, will the entire constellation of contacts be ''correct.'' At other sites, in general, the interactions will never be strong enough to prevent the repressor from dissociating. It is notable that many repressors that have been characterized bind to operator sites that are slightly suboptimal in terms of binding affinity (i.e. in the number of intermolecular contacts that can be made). Presumably this is because the cell requires rapid dissociation of the less tightly bound repressor–operator complexes when environmental conditions call for derepression. Clearly, there must be a sliding scale of affinities between very poor (noncognate sites) and high affinity (but not necessarily perfect) operators.

Recognition of the ability of repressors to bind nonspecific DNA sequences and the problem of locating a single unique sequence among millions of competing sites raises the question of the time taken by the repressor to locate its operator. Experimental measurements of the kinetics of repressor–operator complex formation (see Sect. 2.1) show that the process is extremely rapid despite these difficulties. It appears that repressors can use one or both of two approaches to solve the search problem. In each case, the mechanism relies on the repressor maintaining contact with the DNA during the movement from one potential operator site to another. The first is termed ''sliding'' and involves lateral movement of the repressor along the DNA. At each interval (1 bp) during the slide, the repressor is, therefore, able to check a new sequence for a match to its operator. The second mechanism is termed ''intersegment transfer'' and involves the transient binding of two different segments of DNA duplex by one repressor molecule. The repressor can then ''hop'' between different regions of the DNA molecule. In reality, it appears that a combination of these two mechanisms may be used, dramatically increasing the speed of operator site location (Fig. 11).

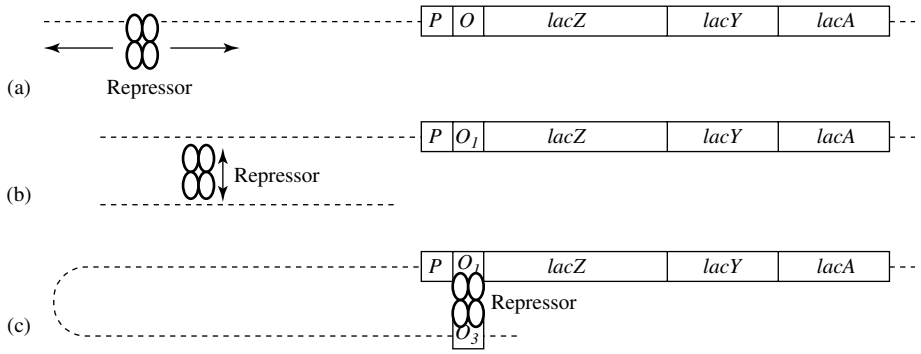

Fig. 11 Cartoon illustrating facilitated diffusion. (a) Lac repressor bound nonsequence-specifically to DNA can search for its operator site by sliding along the DNA in either horizontal direction (arrows). (b) Lac repressor can ''jump'' between sections of the bacterial chromosome via an intersegment transfer in which transiently two DNA duplexes are bound. The repressor can remain bound to either duplex when the complex dissociates, as indicated by the arrows. (c) The doubly bound complex is functionally important for repression in the *lac* system. Both DNA segments bound are operator sites, and the result is the formation of a loop of DNA between them.

If the two sections of DNA duplex bound in an ''intersegment transfer'' are part of the same molecule, a loop of DNA is created between the contacted sequences. Oligomeric repressors with more than two subunits appear to use such loops to help achieve their physiological effect. This has been demonstrated most clearly for the tetrameric LacR protein. Analysis of the sequences around the 5′ promoter region for the *lac* operon identified a major (high affinity) LacR binding site (primary operator), which is contacted by two hth motifs from two of the four protein subunits in the repressor. There are also two minor (lower affinity) sites, one further upstream in the nontranscribed sequences and the second downstream from the major operator and actually within the coding region of the first gene of the operon. Either of these secondary sites can also be contacted by the hth motifs of the two remaining LacR subunits forming a loop between the major and minor binding sites. Several possible loops can thus be made, since the repressor can bind only two of the three sites at once. *In vivo*, all the possible loops do form roughly in proportion to the overall affinities of their respective repressor–DNA complexes, and each contributes to the overall level of repression observed.

2 Techniques

The experimental approaches used to study repressor–operator interactions can be distinguished by whether they are *in vitro* or *in vivo* techniques.

2.1 *In Vitro* Techniques for Studying Repressor–Operator Interactions

Repressors have many advantages for *in vitro* studies. For instance, the very high specificity of their interaction with target

operators allows experiments to be carried out with unfractionated protein extracts as well as with purified samples. Normally each bacterial cell would contain at most a few hundred repressor molecules, so studies are most often carried out using recombinant proteins expressed to high levels to facilitate purification. This in turn has led to a dramatic increase in our understanding of the structures and mechanisms of action of these proteins. The techniques of X-ray diffraction and nuclear magnetic resonance (NMR) spectroscopy have been used to determine the three-dimensional structures of repressors and their complexes (see Sect. 1.2). Both techniques require milligram quantities of essentially homogeneous protein or protein–DNA complex. The results make the effort required to produce such samples well worthwhile, allowing a detailed molecular understanding of phenomena such as sequence-specific DNA binding. Although such structural studies are enormously useful in identifying regions of the components that are interacting in the complexes (e.g. the hth motif), they do not provide any information on the interaction energy. It is therefore important to correlate the structural studies with functional experiments aimed at determining the importance of particular interactions to the overall free energy of complex formation. This can be done by varying the nucleotide sequences of test operator fragments and/or by using repressor protein mutants.

The affinities for operator sites are often in the nanomolar range. Thus, experiments require only tiny amounts of protein and usually are performed in conditions of protein excess over operator-containing DNA fragments, which are usually radioactively labeled. One of the commonest techniques used to monitor complex formation is the gel-retardation assay, which separates repressor–operator complexes from unliganded operator DNA fragments by means of electrophoresis in polyacrylamide gels. The repressor–operator complexes are retarded relative to protein-free DNA because of changes in the size/shape/charge of the molecule (Fig. 12). The amount of complex present can then be determined

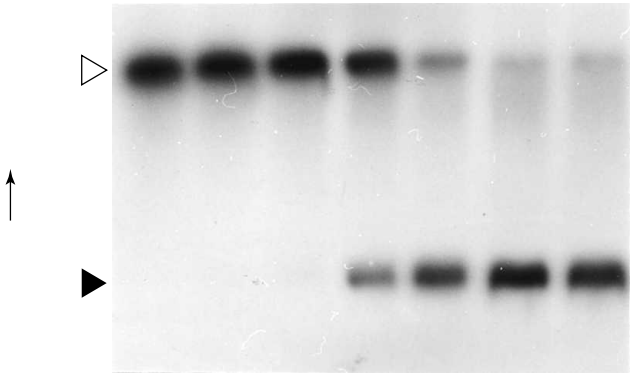

Fig. 12 A photograph of an autoradiograph from a gel retardation assay involving the *met* repressor; arrow indicates direction of electrophoresis. The positions of protein-free operator DNA and the repressor–operator complex are marked by open and solid arrowheads, respectively. Repressor concentrations decrease from left to right.

by autoradiography if radioactively labeled DNA is used. The assay has the advantage of revealing the presence of multiple protein–DNA complexes if they form, but retarded species are observed only if the half-life of the complex is greater than the time required to run the sample into gel (usually ~60 s). Under conditions of protein concentration excess over the DNA target fragment, the concentration of repressor producing 50% retardation of DNA is approximately equal to the equilibrium dissociation constant K'_d allowing quantitative comparisons of repressor–operator affinity to be made.

An alternative method involves fractionation of the repressor–operator complexes by filtration through nitrocellulose, which binds tightly to proteins and their DNA complexes but allows protein-free DNA to pass through. The filtration step is very fast, so problems due to rapid dissociation of the complexes are avoided. It is not possible, however, to determine the relative amounts of multiply-bound DNA fragments, and there are problems associated with the differential retention on the filters of complexes with different stoichiometries.

Although useful for comparative quantitation of repressor–operator interactions, the *in vitro* assays provide no information on the precise sequence of the operator that is being recognized. A series of procedures is available to determine the positions of tight interaction between repressors and the components of the DNA duplex. Some of these techniques can be used in a footprinting mode (i.e. applied to a preexisting complex); others must be used in an interference mode. In the latter, the DNA site is partially modified by a specific reagent before complex formation, and the molecules still capable of being bound by repressor are separated from those in which the modification has interfered with complex formation. In both cases, the experiments are usually performed with DNA radioactively labeled at one end, and the products are analyzed on sequencing gels next to a sequence ladder of the parent fragment for ease of identifying the positions of modification (Fig. 13). Examples of footprinting reagents are DNase 1, which makes single-stranded cuts in the backbone of the target DNA; dimethyl sulfate (DMS), which methylates the N-7 position of guanine in the major groove; hydroxyl radicals, which attack the sugar residues along the duplex; and methidium propyl EDTA, which intercalates between bases before cleaving via a hydroxyl radical mechanism. Binding-interference experiments are often performed with ethyl nitrosourea, which ethylates the DNA phosphate groups, or with hydroxyl radicals or dimethyl sulfate.

The kinetics of operator location can be studied by means of both the nitrocellulose and gel retardation assays. The rate of association or dissociation is monitored, while the size of the target fragment, the salt concentration of the solution, or the overall concentration of DNA is varied. Rates of sliding are affected by the first two variables but will not be affected by DNA concentration. Intersegment transfer, however, is affected by DNA concentration because two duplexes must be bound simultaneously. Care must be taken to characterize the complexes being formed, since quantitative analysis of the binding data is possible only for well-characterized complexes.

Recently a new technique was introduced to measure the kinetics of biomolecular interactions directly, using

the phenomenon of surface plasmon resonance (SPR). The physical principles of this technique are beyond the scope of this article. There are, however, commercial biosensor systems available in which SPR generates a real-time electronic signal proportional to the refractive index of a buffer flowing over the face of a sensor chip to which are immobilized target molecules (e.g. DNA operator fragments) for complex formation. Potential ligands such as repressors are then introduced to the buffer flowing across this surface. When molecules bind to the immobilized target, the resultant refractive index changes give rise to a change in the SPR signal, which can be analyzed to yield a value

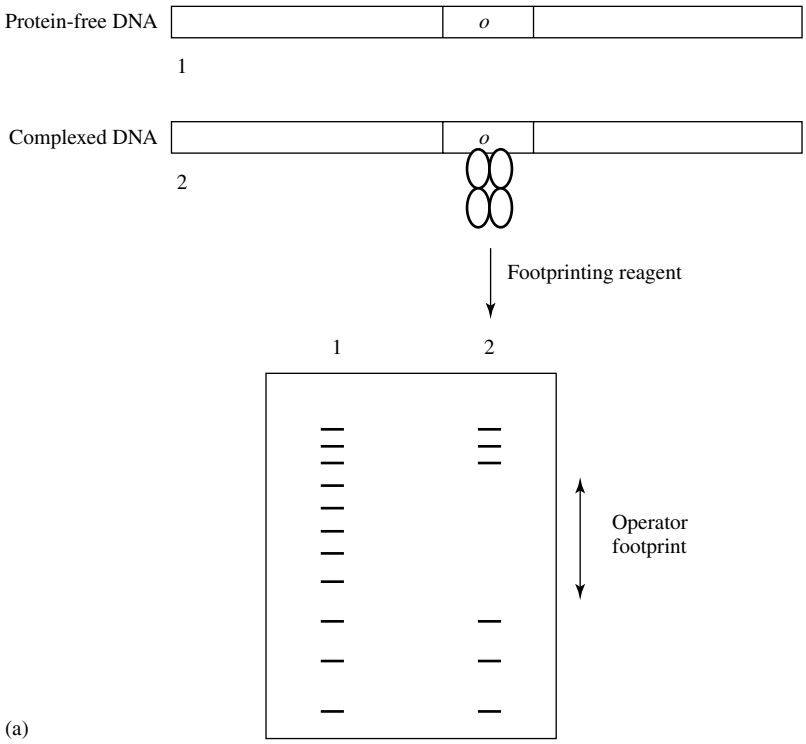

Fig. 13 (a) Footprinting with a reagent that cleaves the DNA at every nucleotide position. The DNA fragment is uniquely radiolabeled at one end, and the resultant DNA fragments are analyzed on a sequencing gel. Formation of the repressor–operator complex protects the bound region from cleavage and results in a blank section on the sequencing gel, which shows the sizes of all the cleaved fragments with respect to the radiolabel at one end.
(b) Modification/binding-interference assay. Radiolabeled, protein-free operator DNAs are modified at base, sugar, or phosphate positions at a level producing approximately one modification per molecule. These DNAs are then used in a gel retardation assay (see Fig. 12) and the bound and free DNAs recovered, cleaved at the sites of modification, and analyzed on a sequencing gel as in (a). In this assay, the blank section of the gel indicates the sites at which modification prevented formation of the repressor–operator complex.

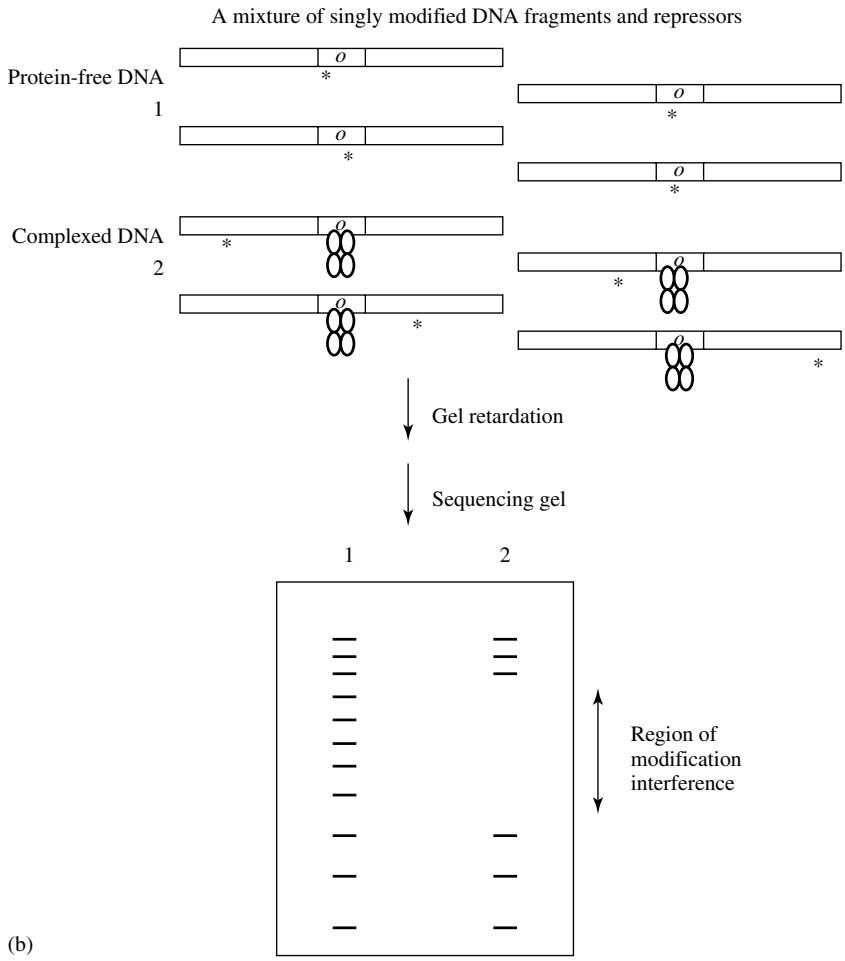

Fig. 13 (*Continued*).

for the association rate constant. The reverse occurs during removal of the bound ligands, giving information on the dissociation rate constant. This technique has the advantage of not involving separation of equilibrium mixtures, not requiring radioactively labeled molecules, and working well with concentrations of macromolecules in the physiological range. Its applications within the field of repressor–operator recognition should grow rapidly in the next few years.

2.2 *In Vivo* Techniques for Studying Repressor–Operator Interactions

Perhaps the most common technique for monitoring repression *in vivo* involves coupling a promoter–operator site to a reporter gene whose product is easily monitored (e.g. β-galactosidase). The levels of repression at a particular site can then be determined by enzymatic assay after lysis of the cells. Techniques have also been

developed to footprint repressor–operator complexes *in vivo*, using reagents (e.g. DMS) that can penetrate living cells. A major problem with both approaches is controlling the concentrations of repressor and operator sites, since they, or their genes, are usually carried on plasmids of variable copy number.

A dramatically new approach to understanding repressor–operator interactions *in vivo* is the use of arrays of immobilized gene fragments to determine the effects of mutational changes on the levels of mRNA transcripts. The arrays can be of whole genes or short oligonucleotide fragments and they can encompass all known open reading frames in an organism. For model organisms whose genomes have been sequenced, these transcriptome analyses allow us to investigate the interconnections between metabolic pathways. An example of this type of analysis for the MetJ repressor is shown in Fig. 14. Two bacterial strains are used; a wild-type

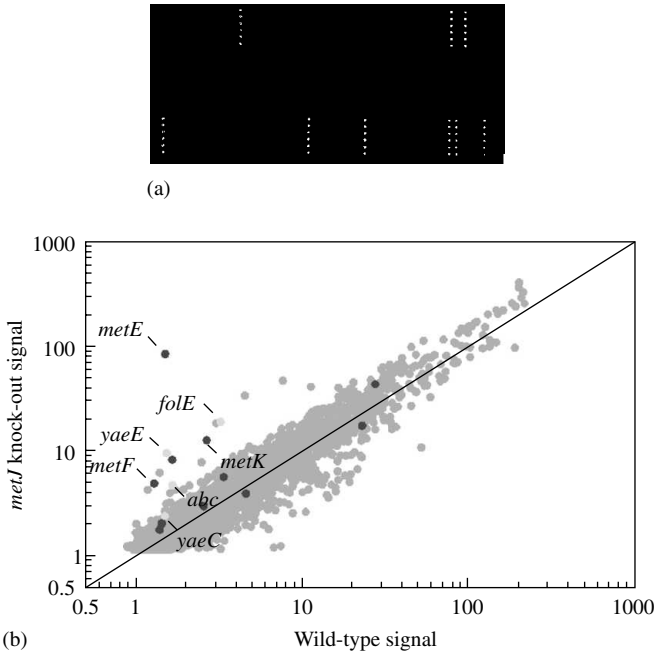

Fig. 14 (a) An example of a hybridized slide showing multiple fluorescent dyes. Columns of spots represent multiple copies of the same target oligonucleotide. Targets whose mRNAs are expressed at different levels in the mutant of interest appear nonblue. (b) Example of a scatterplot of *metJ* knockout versus wild-type (in the presence of methionine). Blue indicates points corresponding to *met* genes, whereas green corresponds to the *folE* and the methionine transport genes, *abc*, *yaeE*, and *yaeC*. The positions of a selection of individual genes are also shown. (c) A schematic showing the steps in the methionine biosynthetic pathway of *E. coli*. The arrows and their sizes show the genes that are regulated above the background as judged from the oligonucleotide hybridization experiment (see color plate p. xxxvi, xxxvii).

reference strain and one containing a mutation within a gene of interest, in this case *metJ*. Cells are grown to a fixed optical density and then total mRNAs are extracted from lysed cells. RNA from each strain is then converted to DNA via reverse transcription using random DNA primers carrying specific fluorophores. By using different fluorophores for the RNAs from each strain, the relative amounts of every mRNA in the cell can be assessed by hybridizing both sets of labelled DNA simultaneously against the array of genomic fragments (Fig. 14(a)). A fluorescence scan of the immobilized, hybridized array can then be used to determine the relative amounts of each mRNA from control and mutant strains. In practice, the amount of each fluorescent dye bound to each point in the array is plotted along an intensity axis such that mRNAs whose levels are identical in the two strains should lie along a diagonal. Genes that are overexpressed relative to the control show as points above this line, while those that are underexpressed are below it (Fig. 14(b); Table 1).

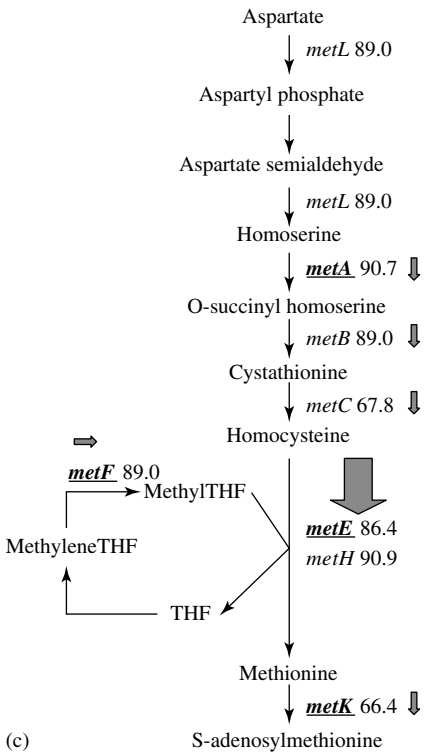

Fig. 14 (*Continued*).

For the *E. coli* methionine repressor, we would expect that mutation of the *metJ* gene, eliminating the repressor protein from the cell, would cause permanent depression of all the MetJ-regulated genes, many of which had been mapped by classical genetic techniques. The operator sites of these various genes are scattered throughout the *E. coli* chromosome; that is, *met* is an example of a regulon. The sequences of the natural operators also vary significantly from the consensus sequence discussed above. The transcriptome analysis shows that although regulated by the same repressor protein, the genes of the methionine biosynthesis pathway are controlled to very different degrees by this system. Measurement of the repressor affinity for these natural operators using techniques described above suggests that despite their sequence differences *in vitro* they all have roughly similar affinities. These results suggest that it is the rate of initiation by the RNA polymerase that determines the levels of repression observed. It is very noticeable also that the strongest repression levels occur toward the end of the *met* pathway (Fig. 14(c)) where most of the intermediates would be turned into methionine or AdoMet. Reduced repression ratios elsewhere in the pathway might have deleterious effects on the use of earlier intermediates in other biosynthetic pathways that would still need to operate when *met* was being repressed.

As well as the classical *met* genes, these studies identify a series of other genes that are clearly regulated by the repressor. One

Tab. 1 Gene expression ratios in the *metJ* knockout strain versus wild-type as determined using gene arrays. The column on the right provides the averages of three independent experiments.

Gene	*Repression ratios*			
	Exp. 1	*Exp. 2*	*Exp. 3*	*Avg.*
metE	38.4	34.6	40.0	37.7
metF	6.6	8.2	8.4	7.8
metK	4.0	5.0	4.8	4.6

metJ	0.4	0.6	0.5	0.5
folE	2.9	4.2	6.8	4.6

of these is *folE*, which controls the biosynthesis of the folate cofactor of the enzymes providing the methyl group that is added to homocysteine. Other regulated genes are involved in transporting methionine into the cell, implying that the levels of free methionine are tightly regulated and that only under conditions of relative starvation would the cell begin to transport methionine from the surrounding medium. Such studies will clearly offer unique insights into the roles of repressor–operator interactions in gene regulation in future.

3 Applications

The primary applications of repressor–operator interactions are in the regulated expression of recombinant proteins in bacteria. The strength of the promoter is also an important consideration. A particularly strong promoter that is used for such experiments is *tac*, which is a hybrid between the *trp* and the *lac-uv5* promoters and is regulated by the LacR repressor. Expression of the regulated gene is induced by the addition of nonhydrolyzable analogs of lactose such as isopropylthiogalactoside (IPTG) to the medium. In this system, the expression occurs at a low level even in the uninduced state, since the promoter is very strong, and if the protein product is poisonous to the host cell, the effect can be deleterious. A common alternative system involves the regulation of the lambda promoter–operator site by a temperature-sensitive mutant λcI repressor. Shifting the bacteria to the nonpermissive temperature results in rapid derepression of the regulated gene.

4 Perspectives

The wealth of information that exists about repressor–operator complexes is being used as a design database for the synthesis of novel reagents capable of binding to the DNA sequence-specifically. There may well be applications for these reagents in the therapeutic control of gene expression, for example, in the treatment of cancers or retroviral diseases such as AIDS. Alternatively, chemically modified versions of several of the repressors described here have been used to achieve sequence-dependent destruction of DNAs. The modifications often involve coupling of reagents capable of cleaving the DNA via reactions similar to those used in footprinting experiments (see Sect. 2.1). The underlying principles of DNA-protein recognition, which are emerging from the study of repressor–operator complexes, will also assist in the design of drugs directed at altering the transcription of particular genes.

Keywords

Activator
A protein that accelerates transcription, generally at the level of promoter recognition, by binding to specific sites that may be at, near, or distant from the promoter region.

Core Transcription Complex
Machinery responsible for initiating the transcription of one strand of DNA from a promoter sequence into an RNA molecule. This complex contains RNA polymerase.

Genome
The information coded in DNA for the expression of all the proteins specific to the phenotype of a given organism.

Promoter
The minimal sequences needed to initiate correct transcription. In prokaryotes, this consists of consensus −35 and −10 regions, spacer regions (18 bp ± 2) between the two, UP (upstream) elements, and upstream activator sequences. In eukaryotes, it often contains TATA box elements and initiation sequences but there is more variation with respect to the nature of the putative TATA region (which may, therefore, be CAAT, GC, or octamer), also these promoters are often assisted by enhancer elements.

Transcription Repressor
A molecule that inhibits transcription generally by sterically interfering with the formation of initiation complexes.

Transcription Factors
Proteins required for recruiting RNA polymerase to the transcription start site to form a preinitiation complex.

Proteins interact with DNA to form nucleoprotein complexes that mediate a host of important cellular processes. Nucleoprotein complexes are at the heart of many processes that include DNA recombination and repair, gene transcription, pathology, viral infection, and in defining DNA accessibility through chromosome structure. The interplay between proteins and DNA is dynamic and must be understood in a time-resolved fashion. Whilst a structural analysis of the individual components of such active complexes is essential, it has to be interpreted within the changing

environment of a cell as it responds to alterations in the environment or as it transits through a preprogrammed cycle of growth, differentiation, and finally but not always, apoptosis. While the number of processes involving nucleoprotein complexes is large, and the mechanisms by which they carry out these functions are many and complex, there is, however, a restricted known set of the structure–function relationships involved. In this chapter, we will attempt to sketch out some of the more common of these, always relating this to possible dynamic changes that occur during the establishment of the nucleoprotein complex or take place during its function. We will pay particular attention to complexes involved in gene regulation at the level of DNA organization and at the level of the control of transcription where the information contained in the genome is decoded to produce the RNA complement that constitutes the transcriptome and hence, the potential proteome of a cell at any given moment.

We have restricted our analysis to nucleoprotein complexes involved in processes in prokaryotic organisms for reasons of expediency, clarity, and because it falls within our own personal range of interest. However, the molecular basis for the formation of specific nucleoprotein complexes is clearly ''system'' independent and will be found across the whole range of living organisms; to paraphrase Jacques Monod ''the same mechanisms present in *E. coli* will be at work in an elephant.'' It's clearly logistically more favorable to study the former than the latter!

1
Protein–DNA Interactions

1.1
Structural Composition of Nucleoprotein Complexes

Proteins are not mere collections of amino acids strung together in a series of chains or globular conglomerates but are modular entities consisting of a select set of three-dimensional structures arranged so as to provide a specific range of functions. In the same sense, DNA is most emphatically not a rod consisting of four bases in a sugar-phosphate backbone double helix, but rather possesses a well-defined local and global structure capable of extensive structural flexibility and of engaging in a myriad of interactions with proteins. Although the potential for the types of interactions is enormous, over the years recurring patterns of specific arrangements have been observed.

1.1.1 Protein Structural Motifs

Protein recognition of DNA sequences involves a wide range of contacts including nonpolar, direct, and indirect (water mediated) hydrogen bonding with DNA bases and direct and water mediated contacts with the sugar-phosphate backbone of the DNA. These interactions may occur in the minor groove or in the major groove or indeed in both grooves simultaneously. The protein structural motifs engaged in these interactions include helix-turn helix, basic leucine zipper (coiled coil) and zinc finger structures, using α-helices, β-sheets, and loops to effect the recognition. A relatively recent study showed that of the three types of interactions characterizing

complexes involving protein residues and DNA, namely, van der Waals contacts, hydrogen bonds, and water mediated bonds, two thirds fell into the category of van der Waals contacts and the remainder was more or less evenly distributed between the other two modes. This rather surprising observation suggests that the simple definition regarding protein–DNA interactions as being specific or nonspecific needs to be examined in some detail. A step in this direction has been made by taking into account the observation that in general a protein is presented to a nucleic acid so as to promote one or both of two distinct types of interaction:

- indirect readout in which the protein recognizes structural characteristics on the DNA;
- direct readout in which there is generally a direct hydrogen-bond distance interaction between amino acids and a given base on the DNA.

The three types of interactions outlined above, however, are in fact present in both these categories and indeed a given nucleoprotein complex may involve both direct and indirect readout. Thus, the distinction between sequence-specific recognition and structural recognition becomes blurred by the dependence of DNA structure on base sequence. The local structure is going to influence the accessibility of bases to the protein. Van der Waals contacts occur mainly with the phosphate backbone of the DNA; some contacts are made with the sugars and a few directly to bases. Water mediated contacts make up nearly 15% of all contacts observed to date and hydrogen bonds, simple, bidentate, and complex, are found essentially between the phosphate backbone and amino acid residues. A rule of thumb is that while the direct hydrogen bonds reflect specific interactions, water mediated and van der Waals contacts act as stabilizing factors and may be useful in allowing the protein in indirect readout of the DNA. However, to date, there are no data that support a simple general code for protein–DNA recognition.

1.1.2 DNA Structures Recognized by DNA-Binding Proteins

There are many types of DNA structures reflecting the myriad ways in which a rod of DNA can be spatially organized through the disposition of the bases with the sugar-phosphate backbone and the orientation of the major and minor grooves. A typical list of such structures would include bent or curved DNA, four-way cruciform junctions, locally melted "bubbles," forked junctions, and so forth. We are going to concentrate on protein binding to bent or curved DNA sequences to investigate some of the salient features of DNA structure recognition by proteins. The insertion of short runs of adenines (A tracts) phased with the double helix in a DNA molecule generally induces a bend by a mechanism that remains elusive but apparently has to accommodate the more or less universally accepted notion that the center of curvature is toward the minor groove of the A tract and toward the major groove of intervening sequences. In other words, one would expect compression of the minor groove within the A tract and compression of the major groove of adjoining sequences. A key question relates to how this structure lends itself to recognition by certain proteins. Answering this question will require a concerted approach that takes into consideration the thermodynamic, kinetic, and structural aspects of the situation.

1.1.3 The Thermodynamics of the Formation of Nucleoprotein Complexes

Since protein–DNA interactions are competitive and noncovalent, the rates and extents of formation of complexes are affected by macromolecular concentrations and by the concentrations of low molecular mass competitors such as electrolytes. There are essentially five interactions that are important in determining the stability and specificity of nucleoprotein complexes. These are the hydrophobic effect, the polyelectrolyte effect, aromatic ring interactions, ionic interactions, and hydrogen bonding interactions. The hydrophobic effect in which the association of nonpolar surfaces is driven by the release of water molecules, and the polyelectrolyte effects that derive from the reduction of the polyelectrolyte charge density at low salt concentrations essentially help reduce the unfavorable noncovalent interaction between uncomplexed macromolecules and a solvent and hence, effectively promote the formation of macromolecular complexes.

Thermodynamically, the strategies adopted to attain a favorable free energy of binding (ΔG_{bind}) are rather varied. Simply stated, the measure of the change in work energy of a system during a reaction, that is, during the formation of a nucleoprotein complex, involves an enthalpic change (ΔH°) and an entropic change $-T\Delta S^\circ$, given by the Gibbs relationship

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \qquad (1)$$

The formation of a nucleoprotein complex should be accompanied by a decrease in ΔG°, that is, $\Delta G^\circ < 0$. It is thus obvious that an enthalpically driven reaction ($\Delta H^\circ < 0$) compensates for an unfavorable entropic change ($-T\Delta S^\circ > 0$) and vice versa. An interesting observation shows that whilst ΔH° and $-T\Delta S^\circ$ values for a number of nucleoprotein complexes involving specific DNA recognition can vary across a broad range ($\sim$60 kcal mol^{-1}), the resulting ΔG° values lie within a small range. This observation that ΔH° and ΔS° do not vary independently has important repercussions. In Table 1, are collected the various molecular processes that are associated with either ΔH° or ΔS°. Although this table is incomplete and oversimplified, it illustrates the combinations available in the play-off between $-T\Delta S^\circ$ and ΔH°.

Strain is obviously a major factor to be taken into consideration. Inducing a distortion on the DNA is clearly enthalpically unfavorable. To unstack a single base pair costs between 7 and 11 kcal mol^{-1}, in the

Tab. 1 Generalized enthalpic or entropic favorability of the main groups of interactions in nucleoprotein and protein–protein contacts. Strain means any configuration for a given atom, molecule or group that deviates from the minimal potential energy for that entity in the free protein or DNA.

Process	*Effect on ΔH°*	*Effect on $-T\Delta S^\circ$*
Hydrogen-bond contacts	Favorable	–
Ion-pair contacts	Favorable	–
Nonpolar contacts	Favorable	–
Desolvation	Unfavorable	Favorable
Strain	Unfavorable	Favorable

case of open complex formation between RNA polymerase and a promoter sequence involving the unstacking of at least 12 bp this could cost up to 77 kcal mol^{-1}. It is clearly expensive and at first sight unfavorable for proteins to choose a binding process that induces strain in the DNA. An attractive proposition as to why proteins have evolved this mechanism is that the induced distortion in the DNA can then be used for other, related processes. In the case of the formation of open complexes with RNA polymerase, the apparent cost of the distortion may already have been met to some extent by topological distortions induced in the DNA by the prior binding of activators.

It seems, however, that nucleoprotein complexes that distort the DNA benefit from a ΔS° driven change in the face of an unfavorable ΔH°, whereas protein–DNA complex formation that does not appreciably distort the DNA is driven by a favorable ΔH° against an unfavorable ΔS°.

How do induced changes in the protein influence the binding characteristics for a given complex? Notwithstanding the many examples that now exist of three-dimensional structures for nucleoprotein complexes, there remains a dearth of concrete data that provide direct insight into this question. Clearly, there is reduced translational and rotational freedom for both the protein and the DNA in the nucleoprotein complex and this will lead to an unfavorable ΔS°. However, in cases in which little distortion of the DNA occurs, then some induced changes in the protein most probably occur and would thus be associated with an unfavorable entropic change. In other words, there may be associated folding changes in the protein during DNA binding, in order to adapt to a given existing structure on the DNA. However, there are no hard and fast rules for predicting the extent of protein rearrangements during binding, and few precise experiments that provide information on this process.

It is worthwhile at this point to examine the phenomena in thermodynamics known as entropy–enthalpy compensation. The fact is that both ΔH and ΔS are temperature dependent. The variation of enthalpy with temperature at constant pressure is given by

$$C_p = \left(\frac{dH}{dT}\right)_p \tag{2}$$

C_p is the molar specific heat capacity for a single compound and is in fact the amount of heat required to raise the temperature of 1 mol by 1 K. Another way of thinking about C_p is to see it as the capacity of a substance to absorb heat energy without increasing the kinetic energy of the substance and thus without increasing the temperature.

Any change in the heat capacity (ΔC_p) between reactants and products in a reaction therefore can be expressed as

$$\Delta C_p = \frac{d(\Delta H)}{dT} \tag{3}$$

Similarly, entropy changes depend on C_p, at equilibrium, $\delta H = T\delta S$, so

$$C_p = \frac{dH}{dT} = \frac{T\,dS}{dT} \tag{4}$$

$$\frac{\Delta C_p}{T} = \frac{d(\Delta S)}{dT} \tag{5}$$

From Eqs. (3) and (5) we can see that integrating from absolute zero to the temperature of interest we can get

$$H = \int C_p\,dT \text{ and } S = \int \frac{C_p}{T\,dT} \tag{6}$$

Thus, if there is a change in heat capacity during a process then both ΔH

and ΔS will be temperature dependent, since $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$, then these effects will effectively cancel, thus producing what is called entropy–enthalpy compensation.

It is curious that most protein–DNA interactions are associated with a strong negative ΔC_p change. Since as mentioned above, DNA-binding proteins may or may not distort the DNA and/or undergo some induced fit during binding, any distortion will presumably be associated with a ΔC_p effect, the entropy–enthalpy compensation may thus play a crucial role and the real synergy that exists between the effect of ΔH and ΔS will need to take into consideration the relationships described by Eq. (6). However, to date, insufficient data are available in order to establish the ground rules for a complete thermodynamic understanding of the formation of nucleoprotein complexes but as the following sections illustrate, techniques are developing that should furnish this information.

2 The Role of Nucleoprotein Complexes in Gene Expression

Gene expression requires intimate interactions between proteins and nucleic acids, and therefore represents an ideal context in which to discuss many of the concepts involved in the formation of nucleoprotein complexes. We are going to concentrate on two aspects of this process; first the process whereby RNA polymerases involved in prokaryotic transcription recognize specific regions of DNA to form competent transcription complexes, and secondly how the spatial organization of the DNA affects this process in the cell.

2.1 The Core Transcription Apparatus

2.1.1 The Initiation Complex

Transcription is the process whereby one of the two strands of DNA are copied into an RNA molecule. The decision to transcribe a given region of DNA is at the core of the regulation of gene expression and thus is a fundamental biological process. The enzymes responsible for transcription are the RNA polymerases. In prokaryotes, RNA polymerase is a relatively large multi-subunit enzyme consisting of 4 subunits $((\alpha)_2, \beta', \beta, \omega, \sigma)$ in the core enzyme and 5 subunits $(((\alpha)_2), \beta', \beta, \omega, \sigma)$ in the holoenzyme. The core enzyme (378 784 Da) consists of the two β (150 625 Da) and β' (155 145 Da) subunits, the dimeric form of the α (36 507 Da) subunit involved in interactions with activators and specific regions on the DNA and the ω subunit. The holoenzyme (449 044 Da), the form that actively recognizes promoter sequences responsible for housekeeping genes, contains the σ^{70} subunit (70 260 Da). Recent three-dimensional structures for the core enzyme and holoenzyme in complexes with DNA have shed considerable light on the structural orientation of the RNA polymerase machinery. However, since the process is essentially a dynamic one, the mechanism by which a σ^{70} containing RNA polymerase operates in order to locate its DNA counterpart, locally separate the two DNA strands, and precisely position the catalytic center at the start site for transcription, is not understood at the molecular level. Without a σ-subunit, *Escherichia coli* RNA polymerase is unable to recognize a promoter sequence. In agreement with the direct contact model originally proposed, several genetic studies have indicated that σ^{70} interacts in a

bipartite manner via its conserved regions 2.4 and 4.2, with two hexameric consensus sequences (separated by 17 (±1 bp)) located around positions −10 and −35 relative to the transcription start site. More recent biochemical evidence has corroborated the interaction with the −10 region and direct cross-linking data have revealed the presence of intimate contacts made by σ^{70} with the DNA in the −35 region.

2.1.2 The Kinetics of Promoter Recognition and Escape

The kinetics of promoter formation is best characterized in prokaryotic systems and we shall first describe this in some depth. We are using this as an example of the predominantly dynamic aspect of protein–DNA interactions in a very basic and important cellular context. Most processes in the cell are not at equilibrium, and understanding these processes requires an appreciation of the kinetics involved and the evolution of the complexes over time, especially in a cellular context. The basic pathway leading to mRNA production is depicted in the following scheme:

$$\mathrm{R} + \mathrm{P} \underset{k_{-1}}{\overset{k_1}{\longleftrightarrow}} \mathrm{RP_c} \underset{k_{-2}}{\overset{k_2}{\longleftrightarrow}} \mathrm{RP_I} \underset{k_{-3}}{\overset{k_3}{\longleftrightarrow}} \mathrm{RP_O} \xrightarrow{\mathrm{NTP}} \mathrm{RP_{init}} \xrightarrow{\mathrm{NTP}} \mathrm{RP_E}$$

In this scheme R, P, and RP represent the RNA polymerase, the promoter containing DNA, and the various RNA polymerase-promoter complexes respectively. RP_C denotes the initial closed complex. RP_I includes all subsequent species in which the DNA in the promoter region remains closed. RP_O signifies complexes that have undergone promoter opening. RP_{init} denotes those species performing the reiterative synthesis of short abortive products. The ensuing escape from the promoter leads to the formation of a stable elongation complex, RP_E. The formation of the initial closed complex (RP_C) involves the specific recognition of conserved promoter sequences. While the −35 hexamer is certainly involved in the initial recognition process, the upstream portion of the −10 element has been implicated as well, since both regions are specifically recognized by σ^{70} as double-stranded DNA. The rate of formation of the RP_C complex may be accelerated by base nonspecific binding mechanisms that allow for two-dimensional sliding along the DNA, ''hopping'' or intersegment transfer between juxtaposed regions of DNA. However, the estimated association rate constants remain in line with a process of three-dimensional diffusion. Moreover, the equilibrium between free RNA polymerase (R) and the RP_C complex (K_B) is extremely rapid at many promoters, meaning that the subsequent isomerization step, and not initial complex formation, is rate-limiting.

However, many promoters are not saturated with RNA polymerase *in vivo*, and can thus be activated at K_B through increased recruitment of the RNA polymerase to the promoter. This most often involves the establishment of contacts between DNA-bound activating proteins and the RNA polymerase that serve to increase binding affinity, although additional DNA–RNA polymerase contacts may also serve this purpose. Activators involved in this step often bind to the DNA upstream of the −35 region, at sites centered on the same side of the DNA helix (the activator protein, CRP – cyclic AMP receptor protein – for example). Thus, RNA polymerase may form favorable interactions between its α-CTD and the activator, which increase initial promoter binding. Alternatively, the

α-CTD can mediate an increase in recognition via contacts with a UP element. Or, DNA-binding proteins (such as the factor for inversion stimulation, the protein FIS) may serve to induce a DNA bend, which brings upstream sequences closer to the RNA polymerase allowing for additional RNA polymerase-DNA interactions. Intrinsic bends in the upstream DNA region can also serve to facilitate promoter binding, presumably by permitting similar interactions between the RNA polymerase and upstream DNA sequences. Such interactions with the upstream region may be sufficient to cause topological distortion in the DNA, thereby explaining the change in linking number observed during the formation of RP_C. Indeed a change of -0.2 (from -1.6 to -1.4 in linking number, or the number of times that two strands cross over) was measured for this transition, and has been interpreted as resulting from DNA bending or conformational change. The ensuing torsion in the DNA could be exploited by the RNA polymerase later in the transcription cycle. In support of this idea, it has been shown that superhelical density also plays a role in determining K_B at some promoters.

The formation of the RP_I complex is believed to include an induced torque in the DNA and/or bending, which introduces an unwinding twist near the transcription start site. Investigations into the effects of supercoiling on promoter usage have suggested that there is an early topological untwisting of 0.3–0.5 of a helical turn, which takes place during the first isomerization (i.e. before promoter opening). These data have lead to the attractive hypothesis that the formation of RP_I aligns the -35 and -10 hexamers on the same side of the DNA helix. Evidence for DNA bending in this complex is provided by scanning atomic force microscopy, native gel band shift analysis and the DNase I hyperreactivity of bases in the vicinity of -38, -48, and the spacer region.

The transition to an open complex (RP_O) is accompanied by DNA strand separation, which is thought to begin within the -10 region followed by propagation downstream past the transcription start site ($+2$ or $+3$). This melting of between 1 and 1.5 turns of DNA thus renders the template strand single stranded and accessible to the initiating NTP (as well as chemical probes such as dimethyl sulfate (DMS), diethyl pyrocarbonate (DEP) and $KMnO_4$). However, the DNA backbone between -10 and $+20$ remains protected from HO radical attack, and the DNase I footprint is unchanged from that of RP_I, indicating that promoter opening occurs without any additional displacement of the RNA polymerase on the DNA. Also the nontemplate strand remains inaccessible to chemical attack.

No external energy source is necessary for the transition to RP_O, making it likely that the RNA polymerase not only lowers the activation energy for DNA strand separation but forms favorable interactions in the open complex as well. As mentioned previously, it has been postulated that some of the required energy comes from the release of a stressed RNA polymerase-DNA intermediate. This intermediate is presumed to be RP_I. Upon release of this strained species, one would expect conformational changes within the RNA polymerase and/or DNA. In support of this idea, during the RP_I to RP_O transition, there was a change noted in the direction of curvature of the DNA entering and exiting the RNA polymerase and in the linking number (from -1.2 in RP_I to -1.8 in RP_O).

In addition to this role in the facilitation of strand opening, interactions with the RNA polymerase are also believed to stabilize the single-stranded region. Indeed, recent studies have demonstrated that the σ^{70} subunit is competent to recognize specifically single-stranded oligodeoxynucleotides corresponding to the nontemplate strand −10 sequence. The binding affinity measured for this sequence was higher when the region was single stranded than for the analogous double-stranded fragment, thereby implicating a single-strand specificity in this interaction

Once the DNA strands have been locally melted and the stable open complex formed, the template strand becomes accessible to incoming nucleoside triphosphates. The nucleotide at position +1 on the template strand will, by Watson–Crick base pairing, determine the identity of the 5′ end of the transcript. The binding of the initiating NTP to the active site serves to stabilize the RNA polymerase–promoter complex, even in the absence of hydrolysis or bond formation. Transcript elongation requires the catalysis of phosphodiester bond formation between the hydroxyl at the current 3′ end, and the subsequent NTP, which will be determined by base pairing with the following nucleotide.

However, a significant proportion of the initiating complexes do not immediately go on to synthesize productive transcript. Instead, these complexes repetitively form and then release small transcripts (up to 10 nt) without either leaving the promoter region or releasing RNA polymerase-promoter contacts. This reiterative process, termed abortive initiation, results in the cyclic formation of short nonproductive mRNAs. These small transcripts dissociate from the stably bound polymerase, leaving the active site free once again to bind the initiating NTP. At each early nucleotide position, the decision between transcript release and continued elongation relies on a kinetic competition between the two processes. It follows that the duration of RNA polymerase stalling on a promoter is determined by the strength of RNA polymerase-promoter contacts as well as flanking promoter sequence. In this way, a promoter with sequences optimized for stability at preceding steps can be hindered by these same contacts during promoter clearance. Therefore, each functional promoter must represent a delicate equilibrium between stable complex formation and facile escape.

Productive mRNA synthesis is only achieved after the RNA polymerase ceases this process and moves downstream of the promoter region. This promoter clearance is thought to require the release of the specific RNA polymerase contacts with the promoter region, accomplished by the separation of the core enzyme from σ^{70} during the RP_{init} to RP_E transition. In accordance with this idea, the size of the DNase I footprint produced by RP_E is considerably diminished in comparison to initiating complexes (20–30 bp vs 65–95 bp). The observed decrease in promoter protection coincides with promoter clearance, indicating that core-σ dissociation occurs at this step. The transcription bubble is also enlarged during this transition, from ~10 to between 17 and 18 nucleotides. The requirement for additional melting of the DNA in the downstream region may also explain the importance of downstream sequence composition in promoter escape.

The resultant elongating complex is incredibly salt tolerant, resisting up to 350 mM NaCl. Thus, the core polymerase in RP_E binds DNA in a fashion that is both extremely stable to dissociation and yet capable of rapid translocation along

the DNA. There is an obvious parallel between this RNA polymerase activity and that displayed by the DNA polymerases. However, there is no apparent analog for the ''sliding clamp'' apparatus for the bacterial RNA polymerases. Numerous studies have probed the conformational changes undergone during the transition by the core subunits themselves. As such it has been proposed that ''jaw-like'' regions of the β' subunit close around the DNA forming close interactions with the downstream sequences.

2.2 Bacterial Chromatin Structure

In simple terms, the decision to express a given gene is, as we have seen above, taken at the level of recognition of promoter sequences by the transcription machinery. This is clearly a complex process involving a number of proteins, some of which are molecular motors, working in a concerted kinetic fashion. However, *in vivo*, this dynamic process takes place against the backdrop of the DNA organization within the cell. Although a lot has been achieved in the study of eukaryotic chromosome structure, our general understanding of the organization and expression of genetic information remains incomplete. The progress of research in bacteria has been hampered in part by a low degree of DNA compaction (albeit around 1000-fold) and resultant instability of the bacterial chromatin. Studies conducted in the paradigm organism *E. coli* revealed that most of the structural proteins of the bacterial nucleoid (Fig. 1) are synthesized in a growth phase-dependent manner.

The relative abundance of several major nucleoid-associated proteins (Fig. 1) in exponential phase is FIS > HU > H-NS > IHF > Lrp, whereas the order of abundance on entry in stationary phase changes to Dps > IHF > HU > H-NS > Lrp > FIS. In organisms like *E. coli* in which HU is composed of two subunits (α and β), the subunit composition also changes as a function of growth phase. This change in the chromosomal protein composition on transition from exponential growth into stationary phase is accompanied by silencing of genome functions. Thus, these proteins not only define the architecture of the bacterial chromosome but also specifically change the pattern of gene expression in a growth phase-dependent manner. This coupling between the modulation of chromosome structure and the pattern of gene expression is further reinforced by the topological fluctuations of DNA during the growth phase and the strong dependence of bacterial promoter activity on DNA topology.

Although the existence of a link between the metabolic reorganization of the cell and the transitions in the architecture of the bacterial chromosome is widely accepted, how the alterations in cellular physiology are coupled with alterations in the topology of the chromosome remains largely unexplored. We will briefly discuss the role of one of the proteins involved in this process – the H-NS protein – in the light of its DNA-binding properties linked to its function as a transcription repressor.

H-NS is an atypical global regulator involved in the expression of genes, which seem to share the common property of being involved in the cells response to changes in the external environment. Modification of the *hns* gene modifies or completely abolishes the expression of around 200 proteins in *E. coli*. H-NS is involved in such diverse functions as the response to osmolarity changes, the use of certain carbon sources, antibiotic resistance, ribosomal RNA regulation,

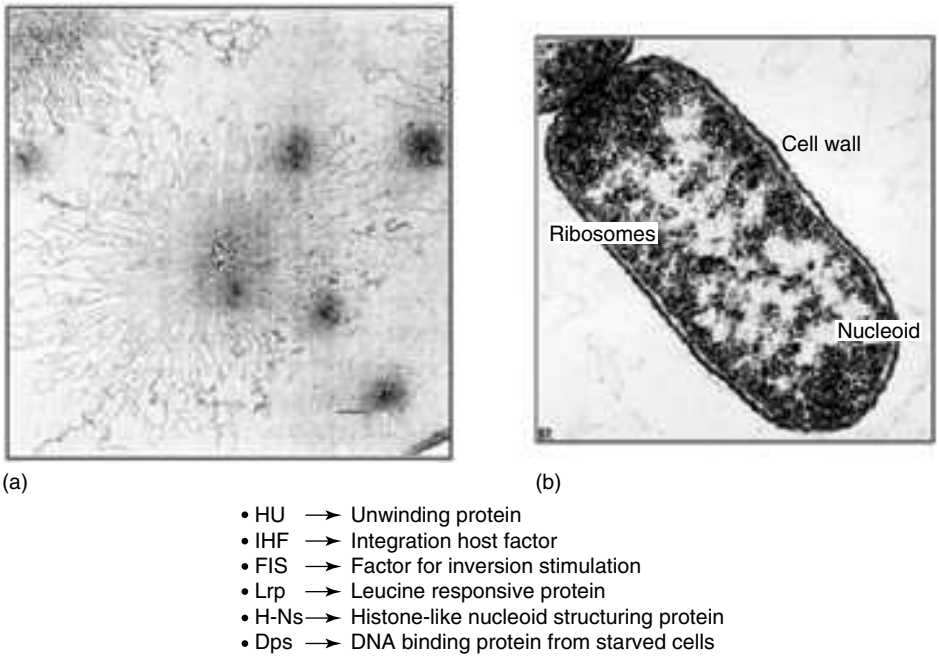

Fig. 1 Structural proteins of the bacterial nucleoid. Electron micrographs of (b) a complete *E. coli* bacterium showing the DNA condensed (the white material) within the cell) and (a) the same cell exploded after salt treatment showing the DNA now completely unwound, note that the horizontal blue bar in (a) shows the length of the original prior to disruption. The organization of the DNA is mostly carried out by the proteins listed (see color plate p. xxxviii).

pili formation, and the activation of virulence genes in pathogenic bacteria. H-NS affects transcription in a differential manner depending on the growth phase, and consequently is strongly involved in the processes of virulence and silencing in bacteria.

Although H-NS does not exhibit a high DNA sequence specificity, H-NS recognizes and preferentially binds to DNA-containing phased A_n tracts that are intrinsically curved. A number of H-NS responsive promoters have indeed been shown to contain regions of intrinsic DNA curvature located either upstream or downstream of the transcription start point. The available data support the idea that the presence of such DNA sequences *in vivo* renders proximal promoters specifically responsive to transcription modulation by H-NS. A crucial question therefore concerns on the nature of the nucleoprotein complexes involving H-NS. A working model for H-NS binding has been proposed in which differential binding to relatively high and low affinity sites occurs. The formation of an H-NS/DNA complex at a region containing high affinity binding sites constitutes a first step of nucleation; this is followed by a buildup of H-NS binding to lower affinity sites on the DNA leading eventually to total occlusion of the DNA by a process of propagation. The high affinity sites clearly require the presence of a singular structural feature and the helical phasing of the recognized

motifs with the periodicity of the DNA. Note, therefore, that specificity of binding is a function of both the intrinsic structure and the deformability of the DNA. An essential feature of this model is that this propagation step is highly dependent on the formation of a ''correct'' nucleation event. How this binding mode is related to the repression of transcription at proximal or distal promoters remains an object of intensive research; however, a plausible mechanism is that the formation of the nucleation step leads to a facilitated coverage of nonspecific sites on the DNA and that interactions between H-NS bound at ''specific'' and ''nonspecific'' sites are responsible for the formation of higher order structures that either physically occlude RNA polymerase from promoter regions (even promoter regions that are not within high affinity H-NS binding-site regions) or provide torsional resistance to the RNA polymerase induced DNA transformations required for the formation of competent transcription complexes. The higher order structure produced by H-NS is most probably not a simple filament that would in general be insufficiently compacted to explain the observed condensation of the DNA, nor would a simple filament explain the phenomenon of silencing in which H-NS is capable of repressing transcription at promoters quite distal to the sites of binding at concentrations incommensurate with the complete coverage of a filamentous DNA. Quite clearly, H-NS is a complex transcriptional regulator exerting its effects through an unusual binding mechanism and forming higher order nucleoprotein complexes. It is to be expected that this mechanism will turn out to be even more intricate when the full nature of interactions between H-NS and other proteins within the bacterial chromatin organization machinery are unraveled.

3
General Methods for Studying Nucleoprotein Complexes

3.1
Chemical and Enzymatic Footprinting

The reactivity of DNA to various chemical and enzymatic reagents has been extensively utilized to probe the local and global structure of DNA in nucleoprotein complexes. The wealth of information that this has yielded has been relatively recently extended by the possibility of applying certain of the techniques in a time-resolved fashion. We will describe the main techniques used in what we call a static (i.e. at equilibrium) and a dynamic (i.e. time resolved) context. We will also try to illustrate attempts to access changes in protein conformation during nucleoprotein complex formation.

Table 2 contains a nonexhaustive list of the reagents that target DNA.

In general, a nucleoprotein complex is treated under specific conditions with the reagent and the products of the reaction examined by denaturing electrophoresis and phosphor imager densitometry. The choice of a specific reagent depends on the nature of the nucleoprotein complex. If knowledge of the position of a protein on a given DNA molecule is required, then DNAse I, exonuclease III, and the more precise hydroxyl radical approach are used. These techniques may also furnish information concerning the quantification of the reaction. The results obtained from attacks by DNAse I are referred to as footprints for the simple reason that the DNA in nucleoprotein complexes will not be accessible to the DNAse I and hence will not be cleaved in those regions of the DNA to which the protein is bound. DNase I, because it cleaves via the minor groove,

Tab. 2 Reagents that target nucleic acids.

Reagent	*Nature*	*Target*
Dnase I	Enzymatic	Phosphodiester bond in sugar-phosphate backbone. Attack via binding in the minor groove. Sequence independent, structure dependent
Exonuclease III	Enzymatic	3′–5′ exonuclease activity, removes mononucleotides. Sequence dependent, structure independent.
Hydroxy radicals	Chemical	Phosphodiester bond in sugar-phosphate backbone. Sequence independent, structure dependent.
Dimethyl sulfate (DMS)	Chemical	N-7 of guanines in major groove. Also cytosines when unpaired in single-stranded DNA. Sequence dependent, structure dependent.
Diethyl pyrocarbonate (DEP)	Chemical	Carboxyethylates N-7 of imidazole ring of purine residues in distorted DNA (deviation from classical B-form). Sequence dependent, structure dependent.
Potassium permanganate ($KmnO_4$)	Chemical	Oxidizes nonsaturated double bonds to vicinal diols, reacts preferentially with thymines. Sequence dependent, structure dependent.
Osmium tetroxide (OsO_4)	Chemical	Unstacked thymines. Sequence dependent, structure dependent.
1,10-Phenanthroline-copper	Chemical	Cleaves phosphodiester backbone through minor groove. Sequence independent, structure dependent.
Singlet oxygen	Chemical	Generated by irradiation of eosin isothiocyanate in the presence of Tris, singlet oxygen diffuses into the DNA and modifies bases. Sequence independent, structure dependent.
UV laser	Photonic	Photochemical rearrangement of bases, leads primarily to pyrimidine dimer formation and other rearrangements generally involving guanine residues. Sequence dependent, structure dependent.

will produce enhanced cleavage at those regions of the DNA possessing a widened minor groove. Thus, by looking at DNAse I cleavage patterns one can deduce, not only that region occupied by the protein but also those regions in which the DNA has been distorted leading to a widened minor groove.

Sometimes it is useful to probe changes in the local conformation of the DNA. In these cases, reagents that react with unusual configurations are used. Potassium permanganate, for example, which oxidizes unsaturated bonds in pyrimidines, reacts almost exclusively with thymines in which unstacking between a thymine and an adjacent base on the same DNA strand has exposed the 5–6 double bond containing the vicinal diols. Oxidation of thymines produces a labile DNA molecule that may be cleaved at the sugar-phosphate bond adjacent to the modified base. Such modifications may then be visualized, as for DNaseI cleavage, by the use of end-labeled DNA and separation on denaturing polyacrylamide sequencing gels. Consequently, where there is a local change in DNA structure (such as local melting of the DNA strands, characteristic of the formation of an initiating transcription complex

with RNA polymerase), the extent of distortion may be determined by the relative reactivity of the thymines to $KMnO_4$. Similarly, the reactivity of cytosines (DMS), adenines (DEP) (Table 2), and thymines (OsO_4) may be examined in different nucleoprotein contexts. 1,10-Phenanthroline-copper is a reagent that intercalates in the minor groove of DNA and can, under specific conditions, generate radicals that then cleave the sugar-phosphate backbone. It, therefore, provides information on the relative geometry of the DNA, that is, the minor groove, at specific points on the DNA. One can generate singlet oxygen molecules, which then migrate into the DNA and modify bases; the modified bases render the DNA suitable for cleavage in a similar fashion to the chemical modification ($KMnO_4$ etc.), and thus the site of modification may be simply ascertained.

The use of a reagent is limited by two considerations, the spatial resolution provided by the probe (DNAse I, for example, needs to bind in the minor groove and also requires a specific binding region on the DNA, which therefore limits the spatial resolution of the ensuing footprint), and the degree of perturbation of the nucleoprotein complex by the probe itself. Eosin isothiocyanate, used to generate singlet oxygen, actually very strongly perturbs many nucleoprotein complexes and thus one has to be sure that the structure that is being hit by the reagent is not in fact an artifact due to rearrangements in the nucleoprotein complex induced by the reagent itself.

The judicious use of these types of reagents provides useful information about the local structure of the DNA in these complexes. Indeed, these reagents have provided enormous insights into many, by now classical structures, ranging from cruciforms, and Holliday junctions to transcription initiation complexes.

In cases in which the formation of a nucleoprotein complex occurs over a timescale in excess of tens or hundreds of milliseconds, quite a few of the techniques listed in Table 2 are sufficiently rapid that they may be used to probe changes taking place during this process. This is an extremely important and powerful approach since many of the processes involving nucleoprotein complexes are practically irreversible and knowledge of the kinetics of these processes is essential for a full understanding of the mechanisms involved. Table 3 illustrates how three of the techniques used to probe DNA may be used in a time-resolved fashion.

3.2 Electromobility Shift Assay

The basis of the electromobility shift or more commonly called band shift assay is that protein–DNA complexes remain intact during migration in gel electrophoresis and thus appear as distinctly more slower moving bands than the free DNA fragment. The assay is simple and quick, and the use of radioactive binding-site DNA makes it highly sensitive. It can be used for both highly sequence-specific and nonspecific proteins, such as histones. Band shift assays can be used quantitatively to estimate dissociation constants for protein–DNA complexes. Additionally, band shift experiments can be used to visualize protein–protein interactions between a DNA-binding protein and other non-DNA-binding proteins. The binding of a second protein to a protein–DNA complex to form a triple complex is visualized by a further retardation of mobility that is called a *super shift*. Super shift experiments can

Tab. 3 Some time-resolved methods to study the kinetics of DNA–protein interactions.

Method	*Target and spatial resolution*	*Time resolution*	*Advantages*	*Disadvantages*
UV laser photofootprinting	van der Waals contacts, T-dimers	~10 ns	ns pulses no need to add any reagents	DNA damage only < 2 Å low quantum yield
DNase I footprinting	Protection and hypersensitive sites	30 ms	Strong signal	Needs Mg^{2+} large footprint
OH X-ray footprinting	Solvent accessibility of bases (amino acids)	3 ms	Single base resolution no need to add any reagents	Sensitive to quenchers such as glycerol and Tris buffer

also be used to assay the binding of a second DNA-binding protein to the DNA or the binding of a second molecule of DNA to the protein.

The band shift assay can be used simply to estimate dissociation constants for nucleoprotein complexes involving just one protein and its binding site. Two methods are generally used; in the first the protein concentration needs to be known accurately, whereas in the second method both the protein and the DNA concentrations are required. In both methods, the amount of free DNA and the amount of DNA bound in the protein–DNA complex have to be estimated either by measuring the intensity of a band in an auto radiograph using techniques such as classical densitometry, or more commonly nowadays, phosphor imaging. An important caveat when using the band shift assay is that association rate constants may be altered by the concentrating influence of the so-called cage effect of the polyacrylamide gel and that dissociation of the complexes may be drastically affected by the change in buffer conditions as the complex enters the gel. The net result may well be important deviations from equilibrium and thus band shift assays are most useful for comparative studies rather than for obtaining absolute equilibrium values.

The first method involves the use of a low DNA concentration (below the dissociation constant) compared to a relatively large range of protein concentration. Since, in a simple situation in which a protein P binds to a DNA-binding site D, the concentration of nucleoprotein complex [PD] is related to the dissociation constant K_D by

$$K_D = \frac{[P][D]}{[PD]} \text{ such that when}$$

$$[D] \leq\leq K_D \text{ then } [P]_{free} \cong [P]_{total}$$

and so $K_D = ([P]_{total}\cdot[D])/[PD]$ in other words, when the concentration of DNA is equal to the concentration of the protein–DNA complex (50% complex formation) then the dissociation constant is given by the total protein concentration.

The second method for determining dissociation constants requires the preparation of a range of different concentrations of a one-to-one molar mix of protein and DNA. The proportion of DNA in the complex at the different concentrations depends upon the ratio between the

total DNA concentration and the dissociation constant. The most convenient way to perform this measurement is to titrate (labeled) DNA at high concentrations (i.e. at least 1000 times the estimated dissociation constant) with increasing amounts of protein. Analysis of a band shift gel allows the determination of the point at which a one-to-one complex is formed. Subsequently, a one-to-one complex, formed under these conditions, is diluted serially and the analysis repeated at different DNA concentrations to estimate the percentage of complex. The concentration of complex is dependent upon the dissociation constant and the concentration of DNA, since in the equilibrium

$$P + D \longleftrightarrow PD$$

$$K_D = \frac{[P]_{free} \cdot [D]_{free}}{[PD]} \quad (7)$$

and

$$[D]_{total} = [PD] + [D]_{free} \quad (8)$$

since the required condition is that

$$[P]_{total} = [D]_{total} \quad (9)$$

then

$$[P]_{free} = [D]_{free} \quad (10)$$

and

$$K_D = \frac{([D]_{total} - [PD])^2}{[PD]} \quad (11)$$

so

$$[PD]^2 - (2[D]_{total} + K_D)[PD] + [D]^2_{total} = 0 \quad (12)$$

then

$$[PD] = \frac{(2[D]_{total} + K_D) - \sqrt{(2[D]_{total} + K_D)^2 - 4[D]^2_{total}}}{2} \quad (13)$$

It must be emphasized that the apparent K_D values obtained are primarily of use in a comparative sense rather than to allow a rigorous thermodynamic analysis.

3.3 Cross-linking of Nucleoprotein Complexes

3.3.1 Formaldehyde Cross-linking

Formaldehyde is a highly reactive reagent that produces protein–DNA and protein–protein cross-links between macromolecules in close contact. The distance between the cross-linking groups of protein and DNA should be around 2 Å suggesting an interaction at the range of van der Waals radii. Therefore, the formaldehyde cross-linking procedure allows identification of proteins and protein domains in close proximity to the DNA. Formaldehyde cross-linking had been widely used for studies of protein–DNA interactions in chromatin *in vivo* as described in detail. Although the reaction of formaldehyde with nucleotides and DNA is well characterized, the exact mechanism of the cross-linking reaction between proteins and DNA is not well known. It was shown that formaldehyde reacts with the amino groups of cytosines, guanines, and adenines and the imino groups of thymines and probably guanines. In proteins, potential candidates for cross-linking are lysine, arginine, tryptophan, and histidine residues. The first stage includes the reaction with amino or imino groups and results in the formation of methylol derivatives that react with the adjacent second reacting group. In conditions in which short cross-linking times are used and cross-links occur only in the melted DNA regions, the imino groups of thymine (or guanine) bases are highly probable targets of cross-linking reaction. This assumption is based on two known observations:

- Kinetic studies demonstrated slow formaldehyde reaction rates with amino

groups while reaction rates of imino group were fast.
- Reactions with the amino groups of purines can take place with double-stranded DNA as well as with melted DNA regions, while the reaction with imino groups of thymine occurs only in melted DNA regions.

The product of the first reaction step (methylol derivative) is very unstable while the final cross-linked derivatives are stable at 24 °C. Cross-linked complexes of RNA polymerase subunits can be incubated for several hours at room temperature without significant degradation. At 50 °C, slow degradation of protein–DNA cross-links was detected after 20 min of incubation in Tris-HCl containing buffer ($t_{1/2}$ = 90 min). Incubation for 2 min at 95 °C leads to full disruption of the cross-links.

The identification of proteins or subunits cross-linked under different experimental conditions is crucial. Two methods provide simple and direct ways to characterize these contacts. The first method requires polyclonal antibodies to individual proteins or subunits and is a modification of the method used for fractionation of cross-linked chromatin. The method includes precipitation of the cross-linked complexes with subunit-specific antibodies and purification on protein A-Sepharose affinity chromatography. Analysis of bound and nonbound fractions on SDS-PAGE allows the identification of those subunits involved in any particular cross-linked complex. The second method utilizes genetically engineered subunits containing histidine-tags at the carboxyl end or the amino-terminal end. In this case, the cross-linked complexes must be denatured by urea and subjected to fractionation on Ni^{2+}-NTA agarose affinity columns.

3.3.2 Laser UV Cross-linking and Photofootprinting

The intrinsic photoreactivity of DNA and RNA is a useful parameter to measure local DNA structure and identify regions in contact with proteins in given nucleoprotein complexes. In order to satisfy two main criteria of nonperturbation and selectivity, an optimum source of photons must be rapidly delivered to the sample. This is possible by using a UV laser providing high-energy photons (266 nm) in a brief pulse (5 ns) on a small volume of material (10–20 µL). The minimal experimental set up that is required is shown in Fig. 2.

The laser source is a neodymium laser consisting of Nd^{3+} ions at low concentration in yttrium-aluminum-garnet (YAG = $Y_3Al_5O_{12}$) that produces a continuous monochromatic beam at 1064 nm. In Q-switching mode, in conjunction with nonlinear crystals, this beam is quadrupled in frequency to give a homogenous polarized source of photons at 266 nm (approximately 10^{17} photons per pulse proving a dose of around 20–30 mJ per pulse). Since the beam has a diameter of approximately 6 mm, this gives complete irradiation of a solution of 10 to 20 µL at the bottom of an Eppendorf tube. The optimal beam form is a Gaussian rather than a ''doughnut'' configuration. The final 266 nm beam is selected using an array of dichroic mirrors and directed onto the sample using a Pellin–Brocca Prism (Fig. 2). To all intents and purposes, only nucleotide bases are excited at 266 nm. At the photon fluxes used in the setup described in Fig. 2, each base in a solution of DNA, for example, will see at least one photon carrying approximately 4 eV. Under the conditions used here, the ensuing photochemistry is monophotonic and the DNA is not ionized. This is generally confirmed by the absence of nicks

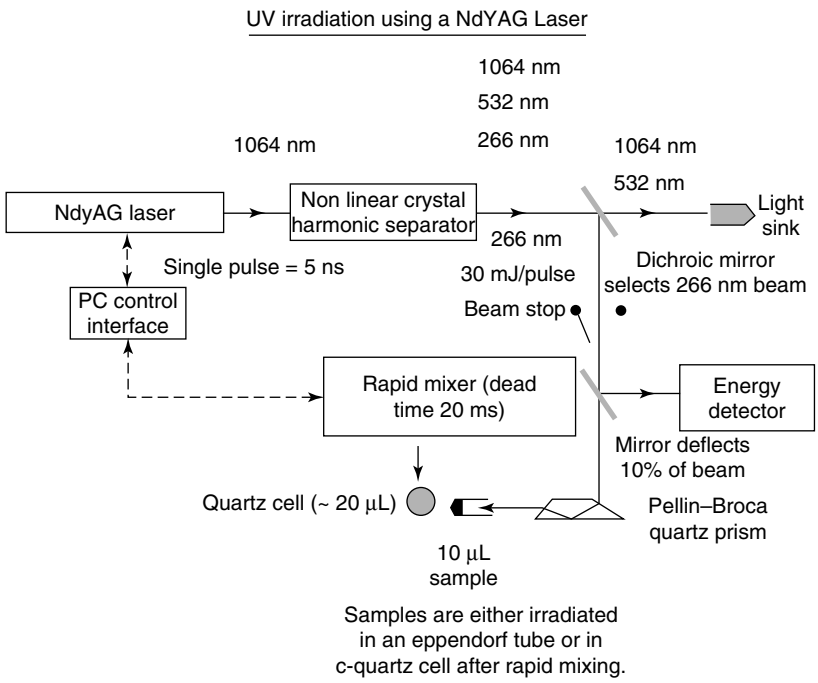

Fig. 2 Typical UV laser set up for the irradiation of nucleoprotein complexes. Complexes may be irradiated in an Eppendorf tube or as they pass through a mixing cell in a stopped flow apparatus.

on DNA strands following irradiation. It should be noted that the ionization energy for thymines is 7.6 eV in water. Furthermore, we can assume that in simple terms, the excited state for the base follows the profile shown in Fig. 3.

Irradiation thus produces excited singlet states of very short (picosecond) duration and a very small proportion of triplet states with longer (μs) lifetimes. In consequence, the photo reactive species are relatively short lived and 98 to 99% are consumed within the 5 ns duration of the laser pulse. What then is the fate of the excited species? There are a number of potential photoreactive products but three in particular are of interest here. The first is the formation of pyrimidine dimers. Adjacent nonsaturated conjugated 5–6 positions in the pyrimidine ring can, following excitation, form covalent cyclic products, notably 4–6 and 5–6 cyclobutanes. The quantum yield for the 4–6 cyclobutanes is around 4%, which essentially means that for a 100 bp DNA, there will be one thymine dimer per molecule following a single pulse at 266 nm. The second event concerns modification of guanine residues. The nature of this reaction is somewhat obscure. The quantum yield may be relatively high and the overall chemistry may require a biphotonic event. The final photochemical event is perhaps the most interesting and involves the formation of covalent links between excited bases and amino acids. The conditions for this cross-linking are that the reactive species are within van der Waals radii distance of each other.

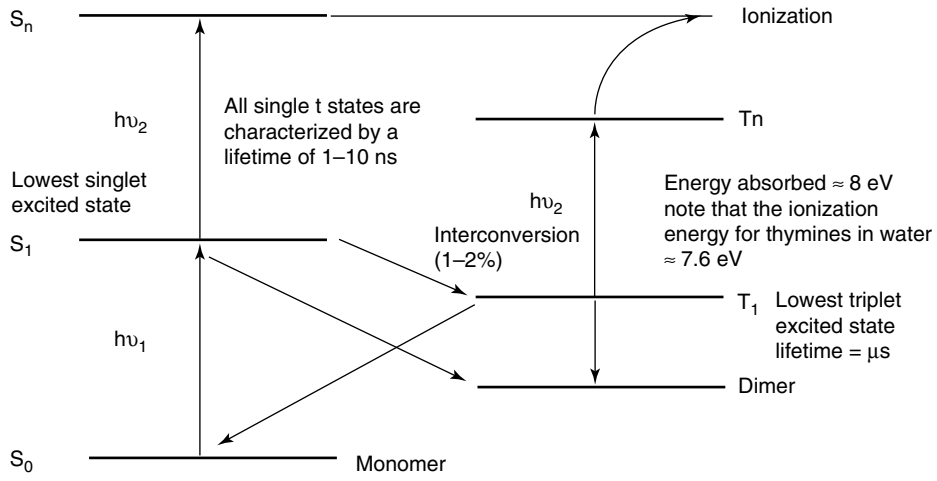

Fig. 3 Electronic states and lifetimes of excited states of atoms in nucleic acids following irradiation. The S1 state is that which is most commonly involved either in cross-linking with amino acids or undergoes internal rearrangement to structures such as pyrimidine dimers, for example.

These limitations arise essentially because of the very short lifetimes of the reactive species (ps). This limitation is of course present for pyrimidine dimer formation and represents one of the major advantages of the technique, namely, that it is extremely rapid, thus reporting configurations that exist before perturbations occur. A simple approach to determine the extent of UV photo-cross-linking to a DNA substrate is to separate the protein–DNA adduct(s) from non–cross-linked DNA by electrophoresis on sodium dodecyl sulfate (SDS)-polyacrylamide gels (SDS-PAGE). Quantification of the separated radio-labeled species is then performed by densitometry, for example, using a PhosphorImager. For most purposes, complexes are formed using 5′-end labeled oligonucleotides (i.e. labeled with (γ-^{32}P)-ATP and polynucleotide kinase). After single-pulse UV irradiation, the samples are separated by SDS-PAGE electrophoresis. The gel matrix should be optimized to allow a clear separation between the protein–DNA adduct and the DNA substrate. The electrophoretic migration of the UV-induced adduct will be dependent on its apparent mass, which, in most cases, equates directly to the sum of the covalently linked components (i.e. the apparent mass of the cross-linked DNA strand plus that of the attached polypeptide chain, calculate approximately 325 Da for each nucleotide of the cross-linked strand). If the DNA fragment is too large to be separated clearly, then an alternative methodology must be considered, for example, by first fragmenting the DNA or by degrading it with a nuclease.

When analyzing cross-linking data, it is important to perform measurements over a range of protein concentrations. This is essential when comparing the relative cross-linking efficiencies of different DNA substrates, since it is the saturation isotherm and not the absolute level of DNA cross-linking that contains the information

on binding affinity. Generally, titrations of fixed concentrations of the oligonucleotide are performed over a gradient of increasing protein concentration. A typical SDS-PAGE gel (visualized by autoradiography) and resulting binding curve analysis is shown in Fig. 4

The progressive fractional saturation of potential DNA-interacting sites is signaled by the increase in adduct formation, measured in terms of the percentage of the total DNA cross-linked (S_{obs}). Maximal cross-linking (S_{max}) is obtained under saturating concentrations of protein in which all the DNA-binding sites are occupied. Adduct formation may thus be represented simply as

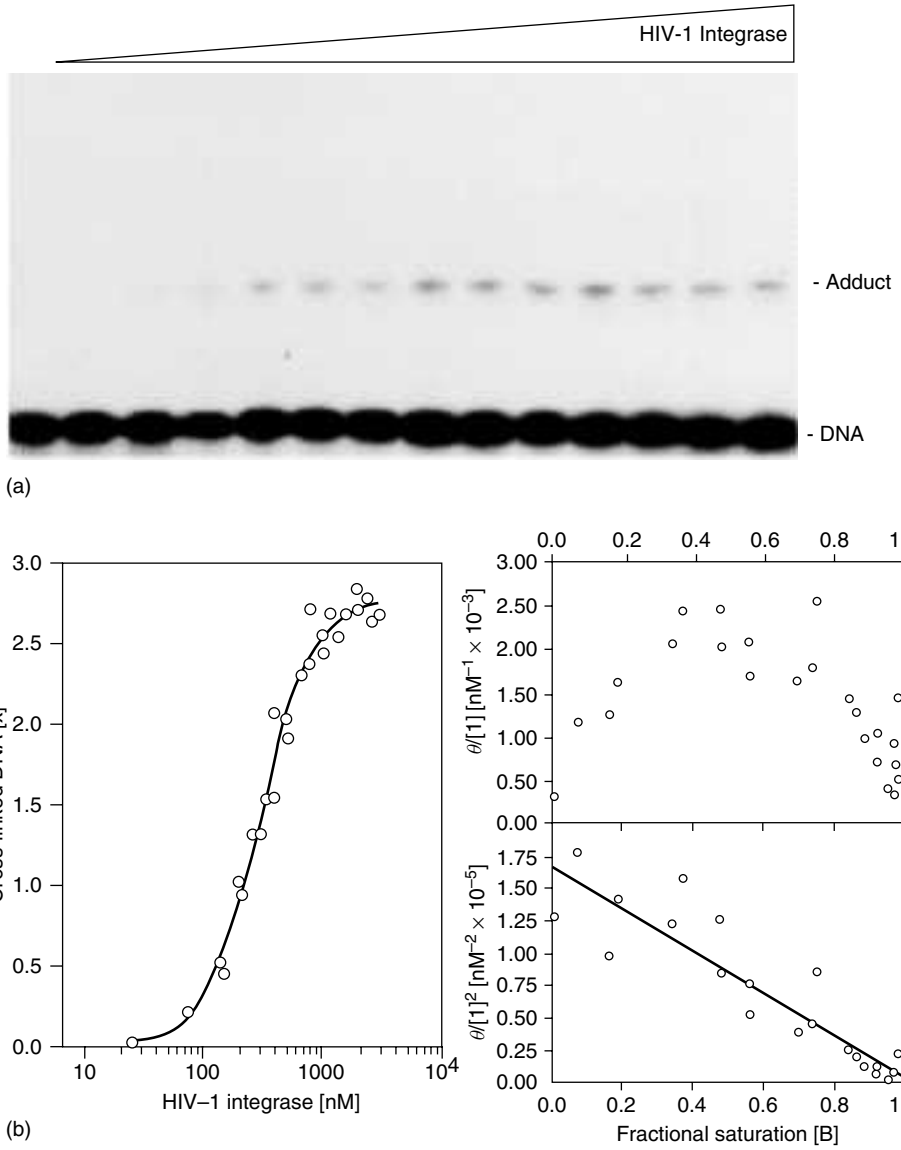
$$S_{obs} = \theta . S_{max} = \theta . \lambda_c \qquad (14)$$

where θ ($= S_{obs}/S_{max}$) denotes the fractional saturation of the DNA lattice and λ_c represents the quantum yield of adduct obtained at saturation of the lattice with ligand, a constant factor dictated by the photochemical reactivity of the oligonucleotide sequence occluded and the number and nature of protein–DNA contacts formed. At 266 nm, λ_c is highly dependent on the base composition of the occluded site. Comparison of the data obtained for two independent proteins (gene32 protein and HIV-1 integrase), both of which are capable of binding non-selectively to ssDNA, indicate that the reactivity of each base may be ordered (relative to dT = 1) as T(1) $\gg$ C(0.04/0.08) $>$ A(0.03/0.04) $\gg$ G($\sim$0). Thus, as a general ''rule-of-thumb,'' pyrimidine residues are more reactive than their purine counterparts, with d(T) by far the most efficient at producing protein–DNA cross-links. Of course, in order for an adduct to form, a close contact must exist between an amino acid and the reactive base. While most amino acids appear capable of cross-linking, the photochemistry is poorly understood and the influence of the side chains on the efficiency of the reaction cannot be predicted for a complex nucleoprotein structure. Least-squares analysis of graphical representations of the degree of cross-linking parameter θ as a function of ligand concentration (Fig. 4) then allows the fractional saturation to be derived. This in turn may then be used to determine binding isotherm characteristics from which an apparent equilibrium constant K_{obs} and apparent stoichiometry may be obtained from curves of the type shown in Fig. 4.

A simple technique for establishing those bases having undergone a specific photoreactivity is that of primer extension. Following irradiation, the bases on a given DNA molecule will have been photomodified and the assumption is that for any given DNA molecule, only one photoactive event will have taken place. Figure 4 illustrates the methodology involved. Essentially, a DNA polymerase such as the Klenow fragment is used to carry out primer extension of end-labeled oligomers along an irradiated template. The Klenow fragment terminates extension at position $n - 1$ with respect to a photomodified base. The photomodification may be pyrimidine dimer formation; intrinsic photomodification of a given base (e.g. G) or the presence of a covalent link with a protein. Products may be easily visualized on denaturing sequencing gels and the extent of photomodification determined using phosphor imager densitometry.

3.4 Surface Plasmon Resonance (SPR)

SPR is a technique that paradoxically measures apparent rate constants for the interaction between an immobilized



ligand and an analyte in solution in order to calculate equilibrium binding constants. The general scope and utility of this approach has been covered in a number of reviews. It is, however, worthwhile here to review the basic principles behind the technique in order to understand its application to studying nucleoprotein complexes. The SPR principles used by the main commercial supplier of this technology (Biacore™) are illustrated in Fig. 5.

Fig. 4 Laser-mediated UV cross-linking of the HIV-1 integrase to DNA. The HIV integrase protein was incubated with a 21-bp duplex DNA molecule (25 nM) for 10 min at 21 °C prior to exposure to a 5-ns pulse of 266 nm UV light. (a) Cross-linked adducts were resolved from un–cross-linked DNA by SDS-polyacrylamide gel electrophoresis. The autoradiograph shows part of a typical titration experiment performed by varying the integrase concentration between 0 and 3 mM. (b) Data points represent the quantification (by phosphor image densitometry) of gels such as the one shown in (a). The sigmoidal curve, shown in semilog form (*panel A*), represents the best fit of the data by nonlinear least-squares procedures in terms of the total HIV-1 integrase concentration and corresponds to a Hill coefficient of 1.90. In *panel B*, the data are transformed, in terms of fractional saturation, to Scatchard form for a first-order (*top*) and second-order (*bottom*) reaction. In this case, the data points are corrected for the bound protein assuming a density of 10 monomers per LTR at saturation. The Hill coefficient is 1.94 after transformation.

Light from a laser source arriving through a prism at a gold surface at the angle of total internal reflection (θ) induces a nonpropagative evanescent wave that penetrates into the flow cell opposite the prism. The intensity of the reflected light is continuously monitored. At a given angle (λ) dependent upon the refractive index of the solution in the flow cell, resonance between the evanescent wave and free electrons in the gold layer results in a reduction in the intensity of reflected light. The change in angle of reduced intensity ($\Delta\lambda$) reflects changes in the refractive index (n) of the solution in the flow cell immediately adjacent to the gold layer. A dextran surface coupled to the gold layer allows immobilization of ligands

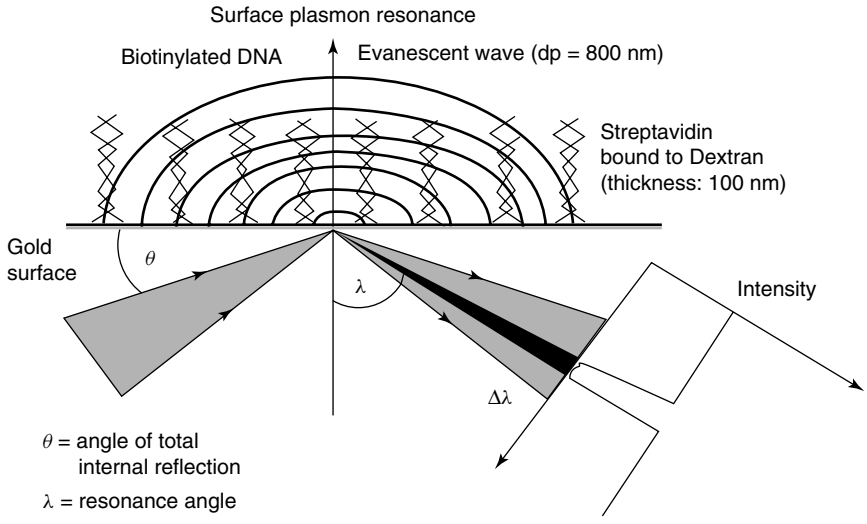


Fig. 5 Basic principles of surface plasmon resonance. In this example, DNA molecules are immobilized through a biotin–streptavidin interaction at the dextran/gold interface. Changes in refractive index as molecules bind to the surface are measured by alterations in the angle λ at which extinction of reflection occurs.

within the evanescent field. In physical terms, the detection system of a typical SPR machine consists of a monochromatic, plane-polarized light source and a photodetector that are connected optically through a glass prism. A thin gold film (50 nm) thick, deposited on one side of the prism, is in contact with the sample solution; this gold film is in turn covered with a long-chain hydroxyalkanethiol, which forms a monolayer (approximately 100-nm thick) at the surface. This layer essentially serves as an attachment point for carboxymethylated dextran chains that create a hydrophilic surface to which ligands can be covalently coupled. Light incident to the back of the metal film is totally internally reflected on to the diode-array detector. A property of this situation is that a nonpropagative evanescent wave penetrates into the solution side of the prism away from the light source. Free electrons in the gold layer enter into resonance with the evanescent wave. In fact, such resonance implies that the amplitude vector characterizing a transversal wave propagating along the gold surface ($\overrightarrow{ksp}$) is equal to the component ($\overrightarrow{kx}$) of the evanescent wave. Since $\varepsilon = n^2$, then if ω is the frequency of the wave and c the speed of light then

$$|\mathbf{kx}| = \frac{\omega}{\mathrm{c}}\sqrt{\frac{\varepsilon_1 - \varepsilon_2}{\varepsilon_1 + \varepsilon_2}} \qquad (15)$$

Furthermore, given that for the evanescent wave:

$$|\mathbf{kx}| = \frac{\omega}{\mathrm{c}}\sin\theta\sqrt{\varepsilon_g} \qquad (16)$$

When resonance occurs, $|\mathbf{ksp}| = |\mathbf{kx}|$ and the intensity of the reflected light decreases at a sharply defined angle of incidence, the SPR angle, given by the simple expression:

$$\sin^2\theta_0 = \frac{\varepsilon_1\varepsilon_2}{\varepsilon_{\mathrm{g}}(\varepsilon_1 + \varepsilon_2)} \qquad (17)$$

Thus θ_0, the SPR angle at which a decrease in the intensity of reflected light occurs, measures the refractive index of the solution in contact with the gold surface and is dependent on several instrumental parameters, for example, the wavelength of the light source and the metal of the film. When these parameters are kept constant, the SPR angle shifts are dependent only on changes in refractive index of a thin layer adjacent to the metal surface. Any increase of material at the surface will cause a successive increase of the SPR angle, which is detected as a shift of the position of the light intensity minimum on the diode array. This change can be monitored over time, thus allowing changes in local concentration to be accurately followed. The SPR angle shifts obtained from different proteins in solution have been correlated to surface concentrations determined from radio-labeling techniques and found to be linear over a wide range of surface concentrations. The instrument output, the resonance signal, is indicated in resonance units (RU); in the Biacore configuration, 1000 RU correspond to a 0.1° shift in the SPR angle and for an average protein this corresponds to a surface concentration change of about 1 ng mm^{-2}. The machine measures refractive index changes (Δn) at or near a surface and relates these to changes in local concentration. This relationship is given by the Clausius–Mossotti form

$$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{N}{3\varepsilon 0}\left(\frac{\alpha + \mu}{kT}\right) \qquad (18)$$

of the Debye equation

$$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{N.\alpha}{3.\varepsilon 0} \qquad (19)$$

where ε is the real part of the dielectric constant or permittivity constant related to the refractive index by $\varepsilon = n^2$, N is the number density given by $N_a\rho/M_a$ (N_a = Avogadro's number, ρ = the density and M_a the molecular mass). It is assumed that $\Delta n/\Delta C$ is a constant.

In general, either the DNA or the protein may be immobilized on the surface and the choice will depend on the nature of the interaction to be studied. It is, however, technically more expedient to immobilize DNA. Whilst a variety of techniques exist for the immobilization of DNA on the dextran surface, the most efficient for the majority of protein/DNA interactions is the use of immobilized streptavidin that can then interact with a suitably end-labeled DNA molecule. While it is often possible to obtain useful binding data pertaining to a specific nucleoprotein complex, it is critical to recall that SPR measurements monitor a steady state rather than equilibrium, that is, a reaction involving two components may form an initial binary complex that then ''evolves'' through intramolecular interactions into a final complex having different dissociation characteristics than that of the intermediate(s) present during the reaction. In many cases now, SPR has furnished useful data concerning specific nucleoprotein complexes and even in complicated cases, such as promoter recognition by RNA polymerase, SPR can furnish useful binding data that correlates well with other footprinting techniques.

An interesting application of this technique toward a more dynamic approach was carried out by using SPR to follow the polymerization of a reverse transcriptase along an immobilized single-stranded DNA template. The resulting change in SPR signal could be closely correlated with the incremental progression of the reverse transcriptase along the immobilized DNA template as it replicated the corresponding RNA or DNA strand. This approach has also been extended to observing RNA polymerases transcribing an immobilized double-stranded DNA template into an RNA molecule and again could be correlated with changes in the population of polymerases on the surface and the appearance of the RNA molecule.

3.5 Microcalorimetry

Microcalorimetry, like SPR, is a noninvasive technique for determining the magnitude of a specific process, such as the formation of a nucleoprotein complex. Microcalorimetry, however, in contrast to SPR, provides access to real thermodynamic measurements of a system at equilibrium. A system at thermodynamic equilibrium is of course defined as one where $\Delta G = 0$. This state is also defined by the equilibrium constant K, where, for a complex AB formed between A and B, $K = [AB]/[A][B]$ (in which case K is known as the *association* or *affinity constant*). This ratio, reflecting the relative probabilities of finding the molecules in a bound or free state, is related to ΔG° by the simple expression

$$K = e^{\left(\frac{-\Delta G^\circ}{RT}\right)} \tag{20}$$

and since

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ, \tag{21}$$

$$K = e^{\left(\frac{-\Delta H^\circ}{RT}\right)} + e^{\left(\frac{-\Delta S^\circ}{R}\right)} \tag{22}$$

This is a form of the familiar van't Hoff equation that allows calculation of ΔH and ΔS by studying the variation of K as a function of temperature.

Microcalorimetry, however, directly measures heat energy changes during a reaction. There are essentially two approaches in use, differential scanning calorimetry (DSC) and isothermal titration calorimetry (ITC). DSC studies changes that occur as the temperature of a reaction is altered, whereas ITC measures thermal changes during the mixing of reactants. Both approaches provide measurements of ΔC_p and thus by the application of relationships like those given in Eqs. (20), (21), and (22) allow calculation of ΔH and ΔS (and thus ΔG and K).

We mentioned above that nucleoprotein complexes are composed of noncovalent interactions and as such the forces that are involved are therefore relatively weak such that the enthalpy changes involved are of the order of 1–25 kcal mol^{-1}. It is to the credit of calorimetric technology and those who use the approach that they are able to measure the changes in the order of differences of 10^{-6} °C associated with these weak changes.

3.6 Fluorescence

Fluorescence-based studies are becoming increasingly popular especially amongst the more biophysically oriented research groups. The advantages offered by this technique include the possibility of being able to carry out studies in solution in a true equilibrium fashion and in many cases in a time-resolved fashion. The dynamic range of sensitivity extends from milli to pico molar and the increased availability of diverse reagents extends the versatility of the approach. There are essentially three fluorescence-based strategies that are currently in use with respect to nucleoprotein complexes.

3.6.1 Fluorescence Intensity Measurements

Changes in fluorescence intensity originally relied on changes in the intrinsic fluorescence of protein upon binding to nucleic acids. Alternatively, fluorescence modified bases such as 2-aminopurine and ethenedeoxy-adenosine or extrinsically labeled nucleic acids have also been extensively used. In general, this latter approach has been favored because of the relatively high quantum yield (i.e. the number of reactant molecules that react for every photon absorbed) allowing good sensitivity.

3.6.2 Fluorescence Anisotropy

A phenomenon that is in fact the basis for dichroism is that the absorption of light by a chromophore depends upon the relative orientation of the absorbing chromophore with respect to the polarization of the light. When the incident light is polarized, then absorption will clearly be more likely for those molecules with chromophores whose transition dipole moments are parallel to the direction of polarization. By transition dipole moment we mean that, for a molecule to be able to absorb or emit a photon of frequency ν, it must possess, albeit transiently, a dipole oscillating at ν. Indeed, it is a property of this phenomenon that the intensity of the transition associated with either absorption or emission of a photon is proportional to the square of the transition dipole moment. In other words, for a transition dipole moment making an angle θ with respect to the direction of light polarization, the molar absorption coefficient ε_0 (also referred to as the extinction coefficient) is given by

$$\frac{\varepsilon_0}{\varepsilon_1} = \cos^2\theta \qquad (23)$$

By using light pulses of short duration and by measuring the fluorescent emission using polarizers, the intensity of emission parallel (I_a) can be compared with the intensity of the emission perpendicular (I_b) to the incident light.

This is very useful since the emission anisotropy may be obtained simply by using the expression

$$A = \frac{I_a - I_b}{I_a + 2I_b} \tag{24}$$

Anisotropy decays exponentially, that is,

$$A_{(t)} = A_{(0)} e^{t/\rho} \tag{25}$$

where ρ is the rotational relaxation time. It is clear that very short ($\sim 10^{-9}$ s) rotational relaxation times may be measured using this technique. Once one has a relaxation time, then it is very straightforward to calculate the hydrated volume V_h for the chromophore-bearing molecule using the simple expression

$$\rho_{(t)} = \frac{\eta V_h}{kT} \tag{26}$$

where η is the viscosity of the solution (J K^{-1} m^{-1} s^{-1}), k is the Boltzmann constant (1.38066×10^{-23} J K^{-1}), and T is the temperature in degrees Kelvin.

The rotational diffusion properties of a labeled oligonucleotide alter during complex formation with a protein thus providing information not only about the nature of the complex being formed but also providing the means of carrying out time-resolved analysis of the formation of the nucleoprotein complex. This latter is an increasingly powerful technique.

3.6.3 Fluorescence Energy Transfer (FRET)

FRET is the nonradiative exchange of excitation energy between two chromophores. In fact, an energy donor in an excited state transfers energy to an acceptor by means of intermolecular long-range dipole–dipole coupling. The quantum yield of transfer, E, depends on the distance (R) between the dyes and is given by

$$E = \frac{1}{1 + ([R]/[R]_0)^6} \tag{27}$$

In practice, although this depends to an extent on the nature of the fluorophore, the effective distance at which the phenomena may be useful is of the order of 4 to 6 nm. So one can see that this technique can be used in a nucleoprotein complex to measure distances between select chromophores and indeed has been applied in looking at changes in nucleic acid structure during complex formation or at putative contact points between RNA polymerases and promoter sequences in DNA.

3.7 Electron Microscopy and Atomic Force Microscopy

Electron and near field microscopy possess the capacity to visualize and follow the average behavior of a population of molecules observed individually and in the case of nucleoprotein complexes provide information concerning DNA curvature and flexibility intrinsic or induced by a protein. In classical electron microscopy (EM), molecules are adsorbed onto a carbon film, which may lead to some loss of three-dimensional information but generally will conserve the macromolecules conformational properties. EM generates data in two broad fields: imaging and analysis. Global electron irradiation of a specimen produces images on a fluorescent screen, a photographic film, or a TV camera. DNA or protein–DNA complexes may be directly adsorbed onto

carbon films or mica supports. Visualization is generally carried out by the use of contrasting procedures that do not interfere with the interactions under study. Thus, samples may be either stained using an evaporated metal coating (such as uranyl acetate) or by using an annular dark field in which the electron beam is tilted to provide a tilted illumination of the specimen and the image resulting from those electrons scattered at wide angles by the heavy atoms present in the sample. Contrast is obtained by impeding direct electrons and allowing only scattered electrons through the aperture. In all cases, direct images of DNA molecules or nucleoprotein complexes may be obtained (Fig. 6).

A useful parallel technique to EM is cryo-EM, which enables visualization

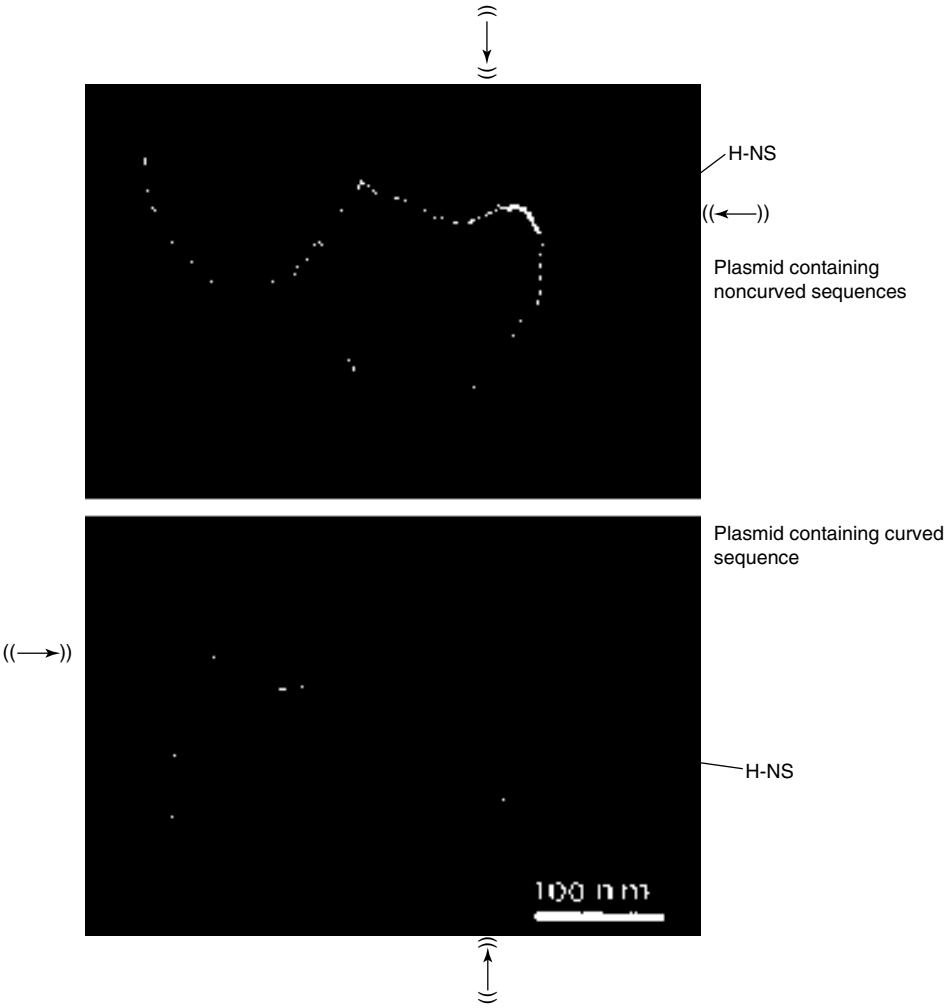

Fig. 6 Electron microscopy of nucleoprotein complexes. H-NS /DNA complexes as visualized by electron microscopy.

of nucleic acids, for example, without staining. A solution of the macromolecules is rapidly frozen to produce a thin film of vitrified water. By using EM, it is possible, in the correct configuration, to visualize molecules floating in the ensuing amorphous solution.

Scanning force microscopy provides a complementary technique to EM possessing high resolution and contrast. In a simple configuration known as contact mode, a flexible cantilever carrying a sharp tip is scanned across a surface. Deflections of the tip as it pans across the sample on the surface may be translated into a topographic image. A second operating mode known as tapping mode exists in which the cantilever oscillates at a high frequency during the scan. The surface topography is then reconstructed from changes in the oscillating amplitude of the cantilever. Nucleoprotein complexes are generally deposited onto a flat mica surface in a suitable buffer, then rinsed and dried under conditions optimized so as not to disturb the conformation of the complexes under study. In practice, this is a major restriction to the technique.

In general, in images formed by 512 × 512 pixels on a 2 μm scan size, each pixel represents a DNA of 3.9 nm or about 11 bp. In the case of nucleoprotein complexes, changes in the measured contour length of DNA molecules due to the presence of bound protein may be interpreted in terms of specific bending or deformation of the DNA.

Keywords

Acrocentric
A type of chromosome in which the centromere is very close to one end.

Autosomes
All of the chromosomes in the genome except for the sex chromosomes (X and Y).

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.
Copyright © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.
ISBN: 3-527-30545-9

Centromere
The structure within each chromosome at which the fibers required to move the chromosomes during meiosis or cell division (mitosis) attach.

Meiosis
The process within the germ cells during which genetic recombination occurs, and in which the number of chromosomes within the egg or sperm is reduced from the 46 found in somatic cells to 23.

Trisomy
The presence in the genome of three rather than two copies of a specific chromosome.

Down syndrome (DS) is the commonest of the genetically caused forms of mental retardation. It occurs with a frequency of approximately 1 per 800 to 1 per 1000 live births, and its incidence increases with increasing maternal age. DS is caused by the presence of an extra chromosome 21 within the genome, which, in turn, results in a 50% increase in the expression of the genes contained on the chromosome. By mechanisms currently undefined, the increased expression of several genes on human chromosome 21 results in a syndrome characterized by mental and growth retardation, a distinctive set of major and minor congenital malformations, a variety of cellular abnormalities, and, later in life, by the development of Alzheimer disease.

1 Phenotype of Down Syndrome

The most immediately apparent, if not the most serious, manifestations of Down syndrome (DS) are the many minor dysmorphic features that collectively constitute its distinctive physical phenotype. Salient among these are upslanting palpebral fissures, epicanthic folds, flat nasal bridge, brachycephaly, short broad hands, incurved fifth fingers, loose skin of the nape of the neck, open mouth with protruding tongue, and transverse palmar creases. Although any individual with DS will have many of the characteristic features and can be easily recognized as having the disorder, none of these features is present in all persons with DS. DS affects the nervous system in three principal ways: hypotonia, which occurs in virtually all newborns and infants; delayed psychomotor development in infancy and mental retardation throughout life; and neuronal degeneration during the adult years. The latter process, which is pathologically identical with Alzheimer disease (presenile and/or senile dementia), results in significant pathologic changes in the brain and may further compromise the already impaired mental functioning. DS is associated with two types of major congenital malformations. Most frequent (about 40%) is congenital heart disease, usually of the endocardial cushion type or one of its variants. Gastrointestinal tract abnormalities occur in

about 4.5% of individuals, more than half of whom have duodenal stenosis or atresia. Structural abnormalities of the thymus and functional defects in T-cell function leading to an increased susceptibility to infection are present, and there is a 10- to 18-times normal incidence of childhood leukemia with a frequent occurrence of acute megakaryoblastic leukemia.

2 Cytogenetics

Down syndrome is the phenotypic manifestation of trisomy 21. As such, it occurs when a third copy of chromosome 21 is present in the genome, either as a free chromosome or as part of a Robertsonian fusion chromosome (in which the long arms of two acrocentric chromosomes are joined at the centromeres). Except in 2 to 4% of cases in which mosaicism, with two populations of cells, one diploid and one trisomic, exists, all cells of the body are trisomic. Although these cytogenetic abnormalities involve most or all of chromosome 21, there are rare cases involving translocations in which only part of the long arm of the chromosome is triplicated. Depending on the region of the chromosome that is involved, such cases may or may not express the classical DS phenotype.

It has long been recognized that the risk of having a child with DS increases with maternal age and that the distribution of maternal age in the population of women having children is the primary determinant of the overall incidence of DS. A variety of estimates of the incidence of DS in the newborn population have been made, and most recent figures are in the vicinity of 1 per 1000. The figures can be broken down to provide maternal age–specific rates per 1000 live births: 0.6 at 20 years, 1.0 at 30 years, 2.6 at 35 years, 9.1 at 40 years, 24.9 at 44 years, and 41.2 at 46 years. Analyses using DNA markers have shown that maternal nondisjunction, the failure of paired chromosomes to separate properly, accounts for 92% of all cases of trisomy 21, 65% occurring at meiosis I, 23% at meiosis II, and 3% postzygotically (at mitosis). Eight percent of cases are paternal in origin, 3% at meiosis I and 5% at meiosis II. A reduced rate of recombination is associated with meiosis I errors and an increased rate with meiosis II errors.

3 Structure of Chromosome 21

Chromosome 21 is an acrocentric chromosome with a genetic length estimated to be 46 cM. It is the smallest of the human autosomes constituting approximately 1.7% of the length of the haploid genome. In physical terms, chromosome 21 is an acrocentric chromosome with the centromere very close to one end and with a very small short arm. The short arm (21p) terminates in a satellite region that may vary in size. Proximal to the satellite is the stalk (secondary constriction) that, as the nucleolar organizer region (NOR), contains multiple copies of the ribosomal RNA genes (*RNR4*) and stains characteristically with silver. The degree of silver staining appears to be a representation of the molecular activity of the ribosomal RNA genes that the chromosome contains. The region of 21p adjacent to the centromere contains highly repeated DNA sequences that consist of the satellite (including alphoid) and the ''724'' families of sequences. None of

these gene families is unique to chromosome 21. It is believed that these families of repeated gene sequences may be involved in the juxtaposition or association of the satellite regions (satellite association) of the acrocentric chromosomes during mitotic metaphase and with the formation of the nucleolus during interphase.

The major part of chromosome 21 is the long arm (21q) that has a characteristic banding pattern consisting of 3 or 4 bands at low resolution and as many as 11 dark and light bands resolvable by prometaphase banding. With one possible exception, all genes of known function (other than those for ribosomal RNA) are located on this arm of chromosome 21, and only this arm is essential for normal development and function. The presence of a Robertsonian fusion chromosome in which the short arms of two acrocentric chromosomes (sometimes both chromosomes 21) are deleted does not cause detectable abnormalities if the genome is otherwise balanced.

The sequence of the long arm of chromosome 21 was completed in 2000 with an estimated 99.7% coverage. This arm has a length of 33.7 Mbp and is relatively gene-poor, with less than half the number of identified genes found on the similarly sized chromosome 22. In the original annotation, it was judged to contain approximately 127 known genes, 98 predicted genes (of which 69% have no similarity to known proteins), and 59 pseudogenes. These numbers have been repeatedly revised as annotation of the sequence has proceeded, and the most recent figures are 178 confirmed and 36 predicted genes. There is evidence that not all expressed genes have been identified and that some predicted genes do not exist. Among the known genes are at least 10 kinases, 5 genes in the ubiquitination pathway, 5 cell adhesion molecules, 7 ion channels, 5 members of the interferon receptor family, and several transcription factors. About 22.4% of the chromosome consists of interspersed Alu sequences and LINE1 elements.

4 Phenotypic Mapping

Cases in which only part of chromosome 21 is triplicated have been intensively studied to arrive at a phenotypic map that will permit a correlation between particular phenotypic features of DS and specific regions or loci on the chromosome. The consensus of studies carried out before molecular markers became available is that the full DS phenotype, as manifested by mental retardation, congenital heart disease, characteristic facial appearance, hand anomalies, and dermatoglyphic changes, appears when band 21q22 is duplicated, and of this, subbands 21q22.1 and probably 21q22.2 are required. Molecular analysis has been used to define the extent of the triplication of regions of chromosome 21, and the results have been used to generate phenotypic maps. Although interpretations vary, it seems clear that many of the phenotypic features appear to be associated with imbalance in the region surrounding and distal to *D21S55*. However, there is also evidence for contributions of genes outside the *D21S55* region, especially in the proximal part of 21q, although the region responsible for congenital heart disease seems to be confined to the distal part of 21q. The genes that, when present in extra copies, contribute to impaired cognition appear to be located in several regions of the chromosome.

5 Pathogenesis

The immediate consequence of an aneuploid state is a gene dosage effect for each of the loci present on the unbalanced chromosome or chromosome segment. Such gene dosage effects have been reported for several chromosome 21 loci. With the exception of the amyloid precursor protein (APP) in the brain from fetuses with DS, and possibly a few other chromosome 21–encoded genes, the measured increase in activities or concentrations in trisomic cells is close to the theoretically expected value of 1.5. Taken in the aggregate, these results confirm the existence of quite precise dosage effects in cells aneuploid for chromosome 21. However, changes in the synthesis of proteins coded for by genes elsewhere in the genome have been observed, presumably as the result of genomic dysregulation resulting from the increased expression of chromosome w31 genes. However, this dysregulation is limited and certainly does not affect the vast majority of expressed genes.

On the basis of studies in animal models (see the following section), decreased platelet serotonin uptake and prostaglandin synthesis, and abnormal myoneural junctions, all of which occur in DS, have been ascribed to increased activity of CuZn-superoxide dismutase (SOD1). With these exceptions, it has not been possible to relate any component of the DS phenotype to overexpression of specific loci. However, a great amount of attention has been devoted to the pathogenesis of the cognitive deficits and Alzheimer disease in DS. The effects of increased expression of several of the loci on chromosome 21 have been considered, and it has been possible to construct plausible explanations for how overexpression of each locus might affect the development, function, and integrity of the central nervous system. A recent case in point is the gene for cystathionine synthase, overexpression of which in DS results in depressed levels of plasma homocysteine. It has been suggested that the altered homocysteine metabolism could compromise the folate-dependent resynthesis of methionine and thereby create a functional folate deficiency, the consequences of which on the central nervous system function could be many. However, in considering such possibilities, it is important to keep in mind that whereas imbalance of an individual locus could well have significant effects on the central nervous system, it is unlikely that it will provide a unitary explanation for the entire range of deficits found in DS. Nevertheless, it is possible that the development of Alzheimer disease in DS is related to the overproduction of APP, perhaps superimposed on an intrinsically defective nervous system.

6 Animal Models

The fact that many of the consequences of aneuploidy in humans arise during the period of morphogenesis and affect the development and function of the central nervous system places special stumbling blocks in the way of their investigation. Research on events occurring during gestation, especially early gestation, is both technically impractical and, currently and for the foreseeable future, ethically and legally impossible. Similarly, there are severe limitations to the study of the central nervous system function in living individuals, and experimental genetic alterations are impossible. It is for this reason that

interest has turned to the development of animal models for DS.

Since ultimate concern is with humans and with human disease, we require models that will duplicate the human condition – in developmental and functional terms – as closely as possible. No model can be an exact one, since no other organism duplicates the human with respect to all of his or her biologic and genetic attributes. Nevertheless, models based on other mammals, which share numerous biologic similarities with humans, seem most appropriate. Primates with the genetic and clinical equivalent of trisomy 21 and DS have been observed but do not offer significant advantages over humans for investigational purposes. Therefore, the mouse has been the model animal of choice for several reasons, including ease of manipulation and genetic control and the similarities to humans in the processes of morphogenesis and probably of central nervous system function, in neurobiological if not psychological terms. Furthermore, despite considerable rearrangement of the mammalian genome, sizable chromosomal regions carrying many genes remain intact and structurally similar in both humans and mice.

Models based on the mouse are not without their problems. It may not always be easy or even possible to obtain postnatally viable animals when sizable regions of the genome are unbalanced. Furthermore, even if it were possible, these animals will never be able to duplicate the higher central nervous system functions, such as cognition, which are so vulnerable to the effects of aneuploidy in humans. As difficult as it is to define mental retardation in an aneuploid human, it is even more difficult to specify the proper functional homology in an aneuploid mouse. Nevertheless, elementary forms of learning are common to all animals with an evolved nervous system, and there appears to be a conservation of the relevant biochemical mechanisms. Therefore, the mouse can be considered to be a legitimate model for learning and memory in humans.

6.1 Trisomic Mice

The modeling of human trisomy 21 in the mouse started at the two ends of the possible spectrum of such models. On one end is the trisomic mouse with an extra copy of mouse chromosome 16, the mouse chromosome that most closely resembles human chromosome 21. At the other extreme is the transgenic mouse with an extra copy or copies of a single human chromosome 21 gene. More recently, however, several intermediate possibilities, with duplications of only parts of mouse chromosome 16 or the insertion of mouse or human yeast artificial chromosome (YAC) transgenes, have been developed.

With perhaps one exception, all the loci in human 21q from the centromere to the *MX1* locus in the distal part of band 21q22.3, approximately 130 to 150 in number, map to the distal part of mouse chromosome 16 (see http://www.informatics.jax.org). The remaining loci, not on mouse chromosome 16, have been mapped to mouse chromosomes 10 and 17. These loci are outside the region shown by phenotypic mapping to be responsible for the facial features of DS. In addition to coding regions, there are also a large number of sequences conserved between the human and mouse genomes that appear to have a functional significance but cannot be identified as protein-coding or RNA genes.

Because of the genetic discrepancies between mouse chromosome 16 and human chromosome 21, trisomy for all of mouse chromosome16, while reproducing much of the genetic imbalance associated with human trisomy 21, results in an overall degree of imbalance that is more extensive than in human trisomy and in an overall phenotype that is more severe. For this reason, the results of studies with mouse trisomy 16 (Ts16) must be viewed with concern insofar as modeling DS is concerned. To correct this situation, segmentally trisomic mice (designated Ts65Dn) in which only the human chromosome 21 orthologous region is triplicated were produced. In these animals, approximately 115 of the original number of 225 genes on human chromosome 21q are represented. The trisomic animals do not have the major anomalies present in Ts16. Rather, their salient phenotypic abnormalities are confined to the craniofacial structures and the central nervous system, although they do exhibit male sterility. As in persons with DS, there is a reduction in the size and granule cell density of the cerebellum, a reduced sensitivity to pain, elevation of brain *myo*-inositol, and abnormalities of the dendritic spines. Although motor learning is normal, Ts65Dn mice have major deficits in learning and behavior, and show abnormalities in long-term potentiation (LTP) and depression and in hippocampal cAMP generation. The pattern of behavioral and learning deficits suggests impairment of both hippocampal spatial learning and of prefrontal functions, and the LTP and cAMP abnormalities are also indicative of hippocampal dysfunction. Further evidence for abnormality of the hippocampus of the Ts65Dn mouse is provided by the presence of giant dendritic spines with aberrant connections in hippocampal neurons and by suppression of LTP by inhibitory inputs. The finding in Ts65Dn mice of an age-dependent loss of function and atrophy of cholinergic neurons in the medial septum of the basal forebrain, which correlates with the loss of cognitive function and appears to be related to an abnormality of nerve growth factor transport, is also consistent with hippocampal dysfunction. It is of note, in this regard, that a reduction in Trk-A immunoreactive cholinergic neurons has been observed in the nucleus basalis of persons with DS.

A second segmentally trisomic mouse, Ts1Cje, is functionally trisomic for the region of mouse chromosome 16 distal to *Sod1*. This trisomy involves about 87 chromosome 21–orthologous genes and still includes the region responsible for the major phenotypic abnormalities in DS. Their learning deficits are similar to but somewhat less severe than those of the Ts65Dn animals. Similarly, there is a reduction in the volume of the cerebellum, but granule cell density is much less affected. However, Ts1Cje animals do not appear to exhibit degeneration of the cholinergic neurons, suggesting that the gene(s) responsible for this phenotype are located in the region of difference between the two segmental trisomies, a region containing about 30 chromosome 21–orthologous genes. A third segmentally trisomic mouse, designated Ms1Ts65, carries a triplication of this region of difference. These animals have only minimal learning deficits, but they are still not normal.

Taken together with the comparison of Ts65Dn and Ts1Cje, the results with Ms1Ts65 indicate that the major genes responsible for the behavioral and learning abnormalities of Ts65Dn mice are located distal to *Sod1*. These studies constitute the first step in phenotypic mapping of the segmental-trisomy DS models

by a subtractive approach in which a known phenotype (as in Ts65Dn) is compared with the phenotype obtained after reduction of the region of trisomy (as in Ts1Cje). The same approach has been used to compare the alterations in craniofacial morphogenesis produced by Ts65Dn and Ts1Cje. Both trisomics demonstrate alterations in the formation of the craniofacial skeleton that are similar to what is observed in DS, with the changes in Ts1Cje being largely the same as those in Ts65Dn. This again demonstrates that the major genes responsible for these skeletal abnormalities in the Ts65Dn mice are located distal to *Sod1*. The ability to generate these various segmental trisomics and to compare their phenotypes directly provides a precedent for the systematic creation of smaller and smaller segmental trisomics and the dissection of the trisomic phenotype.

6.2 Transgenic Mice

In contrast with the formation of trisomic animals, an approach that permits the analysis of the effects of increased dosage of individual human chromosome 21 genes is the construction of transgenic mice. Several strains of such transgenic mice carrying *SOD1*, the gene for human CuZnSOD, have been made and shown to have from 1.6- to 6-fold increased activities of CuZnSOD in the brain and other tissues. Several effects of this increased activity of CuZnSOD that resemble changes found in persons with DS have been found. Transgenic mouse platelets have diminished levels of serotonin and decreased rates of serotonin accumulation that are attributed to a diminished pH gradient across the granule membrane. There is a reduction in prostaglandin E_2 and prostaglandin D_2 biosynthesis in transgenic primary fetal cells and in the cerebellum and hippocampus. The neuromuscular junctions of the transgenic tongue muscles are abnormal, with atrophy, degeneration, withdrawal and destruction of terminal axons, development of multiple small terminals, decreased ratio of terminal axon area to postsynaptic membrane, and hyperplastic secondary folds. Transgenic mice also have anatomical abnormalities of the thymus and premature thymic involution. Impairment of LTP has also been reported.

Many of the abnormalities in transgenic tissues just discussed are presumed to be mediated by alterations in the metabolism of oxygen free radicals resulting from the increased CuZnSOD activity (this enzyme mediates the first step in the ultimate conversion of superoxide anions to water).

Limited work has been done with other types of transgenic mice carrying individual human chromosome 21 genes or their murine homologues. Although they do not develop the full pathology of AD, mice expressing the human APP-751 isoform gene do have diffuse and amorphous extracellular deposits of β-amyloid that resemble those of early AD and manifest deficits in spatial learning. Transgenic mice overexpressing the Ets2 transcription factor develop craniofacial and other skeletal anomalies, with brachycephaly and short necks, thought to resemble anomalies found in DS and mouse Ts16. However, similar anomalies are not found in any of the segmental trisomics of chromosome 16, even though *Ets2* is present in three copies. Overexpression of *HMG14* results in abnormalities of the thymus and epithelial cysts, and mice transgenic for the mouse single-minded gene, *mSim2*, have impaired spatial learning.

The transgenes just described involve loci present on mouse chromosome 16 as

well as human chromosome 21. Therefore, the absence of similar findings in trisomic mice involving the same regions is of concern. The following two loci, however, are represented on mouse chromosome 10, and the trisomy 16 models are, therefore, not relevant. Transgenic mice overexpressing the gene for the protein subunit S100β were reported to be hyperactive, to have learning impairments, and to manifest astrocytosis, axonal proliferation, and a significant loss of dendrites in the hippocampus. Mice overexpressing liver-type phosphofructokinase had elevated activity during fetal life but not during adult life.

Another approach to the generation of transgenic models for DS has been the insertion of genomic segments larger than individual genes in the form of yeast artificial chromosomes. A mouse produced in this manner had abnormalities of learning and behavior too, but less severe than that observed with the segmental trisomies, Ts1Cje and Ts65Dn. Since the major and possibly only gene in the integrated segment of human DNA was the human minibrain gene (*DYRK*), it was suggested that imbalance of this locus is responsible for the observed abnormalities. Support for this inference is provided by mice transgenic for the *Dyrk1A* gene. These animals display delayed neuromotor development and impairment in spatial learning with defective reference memory, findings considered indicative of hippocampal and prefrontal cortex dysfunction.

6.3 Gene Expression Analyses

The cloning and sequencing of both the mouse and human genomes has made it possible to undertake *in situ* hybridization studies of the expression of chromosome 21–orthologous genes in diploid mouse embryos, fetuses, and postnatal animals. Broad expression of the human chromosome 21 orthologues is present in early embryos and becomes more restricted as development proceeds. The number of genes expressed and their patterns of expression differ among tissues, but it is possible to identify several clusters of coexpressing genes. By correlating expression patterns with specific features of the DS phenotype, candidate genes have been proposed for congenital heart and intestinal defects.

Keywords

Polytene Chromosome
Highly replicated chromosomes in an interphase-like chromatin conformation, with each chromatid precisely synapsed with its sisters. This results in a banded structure, permitting high-resolution mapping by light microscopy.

Heterochromatin
A term describing those regions of the chromosome that are highly condensed in metaphase chromosomes and undergo late replication in S-phase. Heterochromatin generally corresponds with those regions of the genome containing simple sequence repetitive, or satellite, DNA. There are few genes in heterochromatic regions.

Euchromatin
Euchromatin corresponds to the single copy and middle repetitive DNA of the genome, in which most of the genes are located. Unlike heterochromatin, euchromatin does polytenize.

In situ Hybridization
Cloned sections of DNA can be accurately mapped to polytene chromosomes by *in situ* hybridization, a process in which chemically or radioactively labeled nucleic acid is hybridized to denatured chromosomes on a microscope slide. Signals are detected immunochemically or by application of a radioactive emulsion.

Balanced Lethal Stocks
Recessive lethal stocks are maintained as balanced stocks, in which the population consists of flies heterozygous for the mutant chromosome and for a corresponding balancer chromosome. Balancer chromosomes possess multiple inversions, which suppress recombination, and several genetic markers, including a dominant visible, and are themselves recessive lethal or sterile, so that balancer homozygotes are either inviable or sterile.

Drosophila melanogaster is arguably one of the most important model organisms available to the modern researcher. This chapter seeks to review the structure of the *Drosophila* genome and the main genetic and molecular techniques currently in use. The *Drosophila* genome has recently been sequenced, and this chapter sets the biology of *Drosophila* in the context of recent updates to the sequence annotation.

1 Introduction

Drosophila melanogaster is arguably the genetically best-characterized metazoan organism. Since its adoption for genetic analysis, its many advantages as a laboratory animal have led to its use as a model system for a wide variety of biomedical researches. The *Drosophila* genome is relatively small, approximately 170×10^6 bp, and is distributed between four pairs of chromosomes. The polytene chromosomes of *Drosophila* have provided a physical map for genetic studies since they were mapped in the 1930s, and continue to be a powerful tool in molecular genetic analysis.

This article describes the features of the *Drosophila* genome relevant to genetic and molecular studies in *Drosophila*.

In the early years of this century, *D. melanogaster* (then known as *Drosophila ampelophila*) was adopted by Thomas Hunt Morgan as an experimental organism in the then new science of genetics. *Drosophila* proved to be an ideal organism for genetic research: it has a short life cycle, 10 to 14 days at 25 °C, and very modest requirements in terms of husbandry. In fact, a modern *Drosophila* laboratory may maintain a thousand or more genetically distinct stocks. Many of the basic concepts of genetics were established using the *Drosophila* species, including important advances in population genetics and evolutionary theory, particularly with *Drosophila pseudoobscura* and related species. However, it is *D. melanogaster* that has made the biggest impact on modern molecular genetic research. With the advent of molecular cloning technology, *Drosophila* found itself ideally placed to benefit from integrated genetics and molecular biology.

As a model organism, *Drosophila* has been an essential tool for the elucidation of basic genetic processes, common to many eukaryotes.

1. For many areas of biomedical research: Examples include aging, neurobiology, embryology, pattern formation, signal transduction, and cell cycle regulation. In particular, research in these areas is facilitated by the sophisticated genetic analysis possible with *Drosophila*.
2. For genome mapping and analysis: *D. melanogaster* has a moderately sized genome, 170×10^6 bp, in comparison with those of yeasts, nematode worms, the mouse, humans, and other species in which large-scale molecular mapping is carried out. Table 1 shows the haploid genome sizes of these species. Thus, the *Drosophila* genome is ideal for use as a model for genome mapping in higher eukaryotes, and additionally has features such as polytene chromosomes, which simplify mapping.
3. Finally, many medically and economically important pests and disease vectors are members of the order Diptera. Examples are the anopheline mosquitoes (malaria vectors), aedine mosquitoes (vectors of yellow and dengue fevers), and the tsetse flies (vector of trypanosomiasis, or sleeping

Tab. 1 The haploid genome sizes of some species.

Organism	*Genome size [$\times 10^6$ bp]*

Saccharomyces cerevisiae	16
Schizosaccharomyces pombe	15
Caenorhabditis elegans	100
Drosophila melanogaster	170
Homo sapiens, *Mus musculus*	3,000

sickness) to name but a few. Several features of the biology and life cycle of these insects mean they are not good research organisms, from the point of view of laboratory culture and genetics. *Drosophila* is a model system for the molecular genetic analysis of these insects.

In this article, I shall review the genetics and molecular biology of *D. melanogaster*, with respect to its use as a model system.

2 An Overview of the *Drosophila* Genome

The haploid genome of *D. melanogaster* is relatively small, 170×10^6 bp, compared with the typical mammalian genome of approximately 3×10^9 bp. *Drosophila* genomic DNA is unmethylated, in contrast to most other higher eukaryotes. The composition of the *Drosophila* genome in terms of single copy and repetitive DNA fractions is presented in Table 2.

About 21% of the genome comprises highly repetitive simple sequence DNA, known as *satellite DNA*. Satellite DNA is present in large blocks of repeated short (5 to 10 bp) units principally located close to centromeric regions. There are several classes of satellite, distinguishable by the repeat unit sequence, and these classes often have chromosome-specific distribution. One satellite, the 1.688 or 359 bp satellite, is atypical, comprising arrays of repeated 359 bp units confined to the X chromosome. In general, satellite DNA is concentrated in heterochromatin, which will be discussed below.

Tab. 2 The composition of the *Drosophila melanogaster* genome.

Single copy sequences	61%	103.7×10^6
Satellite DNA	21%	35.7×10^6
rDNA, histones, etc.	3%	5.1×10^6
Transposable elements	9%	15.3×10^6
Foldback DNA	6%	10.2×10^6
Total genome size	–	170×10^6

A substantial proportion, 18%, of the genome is moderately repetitive. Some of this repetition is due to the ribosomal RNA and histone gene families, but much is accounted for by mobile DNA, or transposable elements. Transposable elements are found in variable, dispersed locations within the genome. Several transposable elements have proven to be very useful in the experimental manipulation and analysis of *Drosophila*, particularly the *P* element, which is described in detail in Sect. 4.2.

The composition of the *Drosophila* genome has, of course, been largely redefined by the successes of the *Drosophila* genome projects, and in particular that of the Berkeley Drosophila Genome Project (BDGP). This will be discussed in some detail below.

3 The Chromosomes of *Drosophila*

3.1 Mitotic Chromosomes

The mitotic chromosome complement of *D. melanogaster* is illustrated diagrammatically in Fig. 1. There are two metacentric autosomes, chromosomes 2 and 3; one tiny dotlike autosome, chromosome 4; and the heteromorphic sex chromosomes, the acrocentric X chromosome and the submetacentric Y chromosome. Sex determination in *D. melanogaster* is based on the ratio of X chromosomes to autosomes. XX individuals have a ratio of 1, and develop as

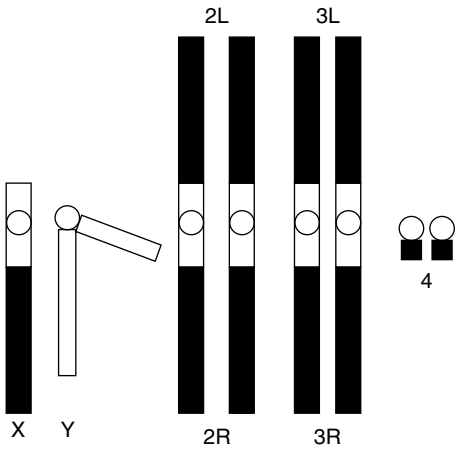

Fig. 1 Diagrammatic representation of the diploid complement of mitotic chromosomes of *D. melanogaster*. The karyotype shown is XY (male). Circles and white boxes represent centromeres and heterochromatin respectively.

females, while XY individuals have a ratio of 0.5, and develop as males. Thus, male *Drosophila* are hemizygous for X-linked loci. XO individuals are male, but sterile, since the Y chromosome carries factors essential for male fertility.

Chromatin can be subdivided on microscopic criteria into heterochromatin and euchromatin, with heterochromatin being characterized by having a highly condensed state and late replication in S-phase. Modern molecular genetic research has shown that, in general, the genes lie in the euchromatin, while the heterochromatin is composed principally of simple sequence repetitive DNA. Indeed, the term heterochromatin is often used as a synonym for satellite DNA. There are exceptions to this rule, including the male fertility factors of the Y chromosome mentioned above, and a few autosomal loci.

3.2 Polytene Chromosomes

In common with many species of Diptera, *Drosophila* possesses polytene chromosomes in several tissues, most notably the larval salivary glands. The salivary glands of third instar larvae are easy to identify and dissect, and their chromosomes are simple to prepare for analysis. Polytene chromosomes are very large, highly replicated chromosomes that are invaluable in genetic research using *Drosophila* (and many other Diptera) as a model.

Polytene chromosomes are found in many species of Diptera including *Drosophila*, where the easiest to work with are found in the salivary glands of the third instar larva. The polytene chromosomes of *Drosophila* represent the euchromatic portion of the genome, in a highly amplified condition, in which each chromatid is replicated approximately 1000-fold, and each copy is precisely aligned, resulting in a highly reproducible transverse banding pattern along the chromosomes (Fig. 2). The pericentromeric heterochromatin, and the heterochromatic Y chromosome remain unpolytenized and are located together with the centromeres in the chromocenter, to which each of the chromosome arms are attached. Thus, the polytene chromosome complement is roughly star shaped, with each major chromosome arm of approximately equal length radiating from the chromocenter.

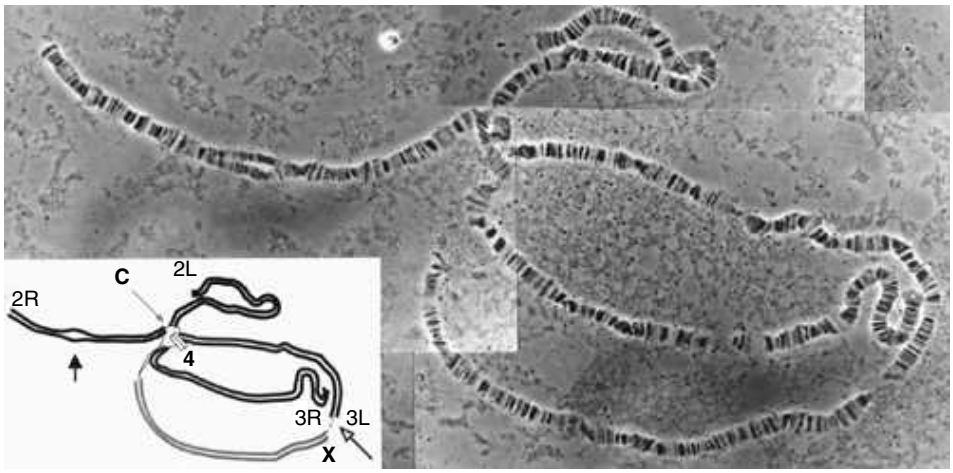

Fig. 2 The polytene chromosomes of *D. melanogaster*. Phase contrast micrograph of a preparation of *D. melanogaster* polytene chromosomes. The specimen has been fixed in 17% lactic acid, 50% acetic acid, and is unstained. Each chromosome arm extends from the chromocenter. Inset: diagrammatic representation of the photograph. Each chromosome arm is labeled. The X chromosome is shaded in light gray, chromosome 2 in dark gray, and chromosome 3 in black, with chromosome 4 in white. **C**: chromocenter, **X**: X chromosome, 2L, 2R: left and right arms of chromosome 2, 3L, 3R: left and right arms of chromosome 3, **4**: chromosome 4. The solid arrow points to a region of asynapsis in arm 2L. The open arrow points to ectopic pairing between the telomeres of 3L and X.

The arm corresponding to chromosome 4 is about 5% of the length of the others. This arrangement is shown in Fig. 2, with a diagrammatic interpretation in the inset.

In the 1930s, the importance of polytene chromosomes for genetic research was realized and highly detailed cytogenetic maps were created on the basis of the banding pattern of the chromosomes. The map devised by Calvin Bridges in the mid-1930s is basically that used to this day, and provides a reference system of map locations understandable by all researchers possessing a copy of the map. Each major arm is divided into 20 divisions numbered 1 to 20 (X chromosome), 21 to 60 (second chromosome), and 61 to 100 (third chromosome). The tiny fourth chromosome is allocated two divisions, 101 and 102. The telomeric divisions are 1, 21, 60, 61, 100, and 102. The numbered divisions are each further broken down into six subdivisions, lettered A to F. This basic map was further refined by Bridges and Bridges to include a number for each band on the map. Thus, each band of the polytene chromosome complement can be unambiguously identified (at least in principle).

Genes identified by mutation can be accurately mapped to the polytene chromosomes using a huge collection of chromosome rearrangements, such as deficiencies, inversions, duplications, transpositions, and translocations. At the simplest level, this involves determining whether a mutant allele is located within a given deficiency (see Sect. 3.3.1).

The resolution afforded by the use of polytene chromosomes is very high;

features of 5 to 100 kb can be recognized on the map by light microscopic analysis, which can rapidly provide positional information at a precision useful by molecular cloning standards. *In situ* hybridization can map cloned segments of DNA to single band resolution, several orders of magnitude better than that easily possible with metaphase chromosomes, and this technique is consequently invaluable for many gene cloning strategies and physical genome mapping projects.

3.3 Chromosome Aberrations

A great many chromosome aberrations, affecting all chromosomes have been recovered and analyzed. The gene and chromosomal aberration data sets of the *Drosophila* database FlyBase contain details of many thousands of chromosomal aberrations. These include the following:

a. *Deficiencies* (Fig. 3). Deficiency is the terminology used in *Drosophila* research for a chromosomal deletion. In a deficiency chromosome, a segment of the chromosome is deleted. In practice, the largest deficiency of practical utility is about one polytene map division. Flies carrying deficiencies larger than this have severely reduced fitness and viability. Furthermore, there are a number of haploinsufficient loci in the genome, which are inviable when hemizygous (e.g. when uncovered by a deficiency). Telomeric deficiencies can be unstable, unless the specialized telomeric sequences have been replaced.

b. *Inversions* (Fig. 3). Inversion chromosomes are those in which a section has been inverted with respect to the wild-type gene order. Inversion and normal chromosomes synapse to form inversion loops, in both meiotic and polytene chromosomes. Chromosomes bearing inversions suppress recombination within the inverted region when heterozygous with wild-type sequence chromosomes. *Balancer chromosomes* are chromosomes carrying several inversions, together with

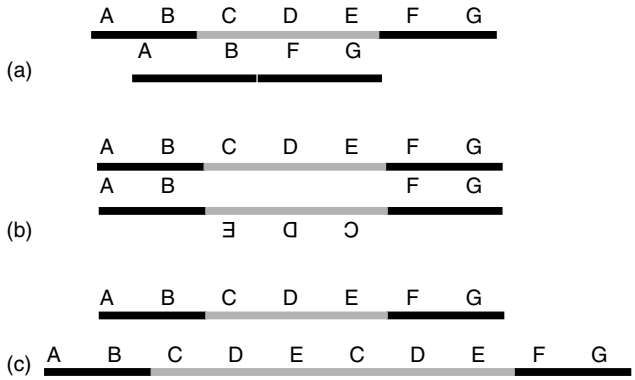

Fig. 3 Chromosome rearrangements. In each panel, a standard order chromosome bearing loci A–G is shown above the rearranged chromosome. The region involved in the rearrangement is shaded. (a) Deficiency. Loci C, D, and E have been deleted. (b) Inversion. Loci C, D, and E have been inverted. (c) Duplication. Loci D, D, and E have been duplicated in tandem.

suitable dominant and recessive markers, and are used to effectively suppress recombination along the whole chromosome. The use of balancer chromosomes is described in Sect. 5.1. Chromosome inversions that contain the centromere are referred to as *pericentric inversions* and those that do not are *paracentric inversions*.

c. *Duplications.* (Fig. 3). These chromosomes carry an additional segment derived from a homologous or other chromosome.
d. *Translocations.* Translocations involve at least two chromosome breaks, and involve the reciprocal interchange of chromosome sections between two or more nonhomologous chromosomes. More than two chromosomes can be rearranged.
e. *Transpositions.* Essentially, a transposition is where a chromosome section is inserted in another chromosome, involving three breaks.
f. *Compound chromosomes.* These chromosomes are derived from the normal chromosome complement by breakage and fusion of chromosome arms. Compound X chromosomes (two X chromosomes sharing a single centromere) affect the pattern of inheritance of normal X and Y chromosomes: in flies of normal karyotype, Y chromosomes are patroclinous (inherited from the father), while in a typical compound X stock, they are matroclinous (inherited from the mother). Compound chromosomes involving the attachment of X and Y chromosomes, whole autosome fusions, and whole autosome arm fusions can be constructed.

The genetic technologies for constructing novel aberrations and compound chromosomes are well established for *D. melanogaster*. Translocations can be combined to create segmental aneuploids, synthetic deficiencies or duplications, when necessitated by the lack of conventional deficiencies for a particular chromosome region. Recombination between inversion chromosomes can also be used to synthesize deficiencies and duplications.

3.3.1 Using Polytene Chromosomes to Map Genes

The principle of deficiency mapping a recessive mutant allele is to test whether a deficiency chromosome "uncovers" the mutation by examining the phenotype of a stock carrying both the deficiency chromosome and the recessive allele-bearing chromosome. If the mutant phenotype is expressed, the locus must lie within the region deleted in the deficiency chromosome (Fig. 4). In addition to simple

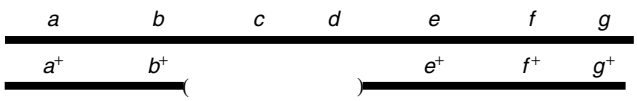

Fig. 4 Deficiency mapping. This figure illustrates the principle of deficiency mapping. A chromosome bearing recessive mutation at several loci (*a* to *g*) is heterozygous with a deficiency chromosome. The region deleted is indicated by parentheses. In this case mutants at loci *c* and *d* will be uncovered by the deficiency, and will display a mutant phenotype. Conversely, loci *a*, *b*, *e*, *f*, and *g* are heterozygous with wild-type alleles on the inversion chromosome and do not display mutant phenotype.

deficiency chromosomes, the *Drosophila* researcher can create "synthetic deficiencies," by combining other, often more complex, rearrangements. If a recessive allele's homozygous phenotype is identical to its hemizygous phenotype, it is likely to be an amorphic (null) allele, while if the hemizygous phenotype is stronger, it is likely to be a hypomorphic allele (see Sect. 5.1.2).

In some cases, a chromosome rearrangement inactivates or otherwise affects the expression of a gene, and can be used to pinpoint that gene's location both cytologically and molecularly.

The polytene chromosome map location of a gene is often a vital prelude to both further genetic analysis and its molecular cloning. This is discussed further in Sect. 3.2.

4 The *Drosophila* Genome Project

The *Drosophila* genome was sequenced by a collaboration of the Berkeley Drosophila Genome Project (BDGP), Celera Genomics, and the European Drosophila Genome Project (EDGP). Since the publication of the original draft sequence in 2000, two further revisions have been published, the most recent at the time of writing being Release 3.0. In Release 3.0, the euchromatin is represented by high quality sequence of 116.8 Mbp, with mere X gaps – in fact chromosome arm 3R is represented by a single contiguous sequence.

Identification of genes in the *Drosophila* genome has been achieved by combined strategy, in which data gleaned by conventional genetic and molecular analyses have been combined with purely computer-based techniques of *in silico* gene prediction. The input of data from conventional sources has been of particular utility in identifying alternatively spliced gene transcripts, and defining the 5′ and 3′ ends of genes.

The total of predicted genes in the *Drosophila* genome is 13 676. This is, perhaps, a rather small number; the nematode worm *C. elegans* appears to have around 19 000 genes, and morphologically at least appears a simpler organism.

4.1 Euchromatin and the Genes

98% of identified genes are located in the euchromatin, with the remainder lying in heterochromatic sequences. The total number of euchromatic genes is 13 379. The average number of exons per gene is 4.6, very similar to the genes of *C. elegans* and the plant *Arabidopsis thaliana*, but considerably fewer than the genes of the human genome (8.9).

Some interesting observations concerning the structure of *Drosophila* genes can be made. Firstly, nesting of genes is common: about 7.5% of genes lie within introns of other genes. Generally, such genes lie in opposite orientation to the gene in which they are located. Similarly, 15% of identified genes overlap another gene. There are 26 cases of genes that are interleaved with another gene. Finally, 48 examples of dicistronic genes – in which two genes with distinct protein products produce a single transcript – have been identified.

4.1.1 Duplicated Genes, Pseudogenes

There are comparatively few examples of duplicated genes and pseudogenes in the *Drosophila* genome. There are a mere 17 examples of pseudogenes identified by the

BDGP, of which 15 are evidently generated by a recombinational mechanism, as they contain introns, and of the remaining examples, one appears to be the result of retrotransposition (it has a poly-A tail and no introns), while the other is so scrambled that its origin cannot be determined.

4.2 Transposable Elements

Transposable elements, or transposons, are segments of DNA that are able to excise from the genome, or replicate, and insert at a second location. These elements fall into the middle repetitive faction of the genome, since they are generally present in copy numbers varying from a few tens to several hundred. *Drosophila* possesses a great many transposable elements (there are 1572 in Release 3 of the *Drosophila* genome sequence), classified into several families on the basis of structure and transposition mechanism. Thus, different strains of *D. melanogaster* have different chromosomal locations for each type of transposable element. The transposition activity of transposable elements can result in a genetic syndrome known as *hybrid dysgenesis*: high mutation rates, high frequency of chromosome rearrangements, sterility, and male recombination (male recombination does not normally occur in *Drosophila*). In general, each type of transposable element displays particular preferred sites of insertion, determined by DNA sequence and other less well-understood factors.

The *P* element is the best-characterized transposable element. Genetically, the activity of this element is seen as hybrid dysgenesis resulting from the cross of *P* element containing (P strain) males with females lacking *P* elements (M strain). Crossing M males with P females does not cause hybrid dysgenesis. Molecular analysis revealed the *P* element to be a 2.9-kb segment of DNA that encodes two proteins: a transposase, and a transposase repressor, depending on alternative splicing of four exons. Transposase is normally only expressed in the germ line. Additionally, the 31-bp terminal repeats of the element and other factors (not encoded by the element) are also required for transposition.

Cloned *P* elements may be injected into *Drosophila* embryos, and will subsequently integrate into the genome. By *in vitro* genetic manipulation, a rich variety of artificial *P* elements have been constructed for use in inserting exogenous DNA into the *Drosophila* germ line. These elements do not themselves encode transposase (so that they will be stable once integrated into the genome) and therefore require a source of transposase, which can be supplied by a defective *P* element encoding transposase, but lacking one or both of the terminal repeats. A more elegant method is to inject embryos of a *Drosophila* strain carrying a stably integrated element expressing transposase. Examples of *P* element derivatives are described below.

1. *Transformation vectors.* One use of germ-line transformation is to provide direct experimental evidence of the identity of a cloned gene. This can be done by determining whether or not a given segment of DNA identified in a cloning project can rescue a mutant phenotype when introduced into the genome by *P* element mediated germ-line transformation. Transformation vectors are defective elements that lack transposase, but possess the terminal repeats. In addition, they have a

selectable marker gene so that genetically transformed flies can be selected or recognized. Typical marker genes include the *Drosophila* gene *white*$^+$, and the bacterial antibiotic resistance gene *neo*^{R}. *white*$^+$ restores wild-type eye color in individuals of *white*$^-$ background, and *neo*^{R} confers resistance to the antibiotic G418, to which *Drosophila* are normally sensitive.

2. *Mutagenesis.* Insertion of a *P* element, or another transposable element often affects that gene's pattern of expression. It is therefore possible to make use of transposon mobilization as a mutagen. Mutants induced in this way present a considerable advantage when the mutated gene is to be cloned. Targeted mutagenesis will be discussed in Sect. 5.1.1.
3. *Enhancer trapping.* *P* elements that contain the *E. coli* *Lac*Z gene lacking a functional promoter sequence have been constructed. Upon insertion, these elements express *Lac*Z only if there is a neighboring gene with an enhancer able to direct expression of the *Lac*Z transgene. *Lac*Z expression is conveniently detected with a histochemical or an immunological assay. Owing in part to the high gene density of the *Drosophila* genome, a large proportion of enhancer trap elements do express *Lac*Z, often in an intricate temporal and spatial pattern that is frequently informative about the nearby gene's identity or function. Enhancer trapping is therefore an efficient means of detecting genes.
4. *The Gal4-UAS system.* This system comprises two distinct element insertions. The first carries the *S. cerevisiae* *Gal4* gene, which encodes a transcription factor that activates transcription from an upstream activating sequence (UAS_{Gal4}). The second element carries the transgene of interest, under the control of the UAS_{Gal4}, and which is therefore expressed only in cells expressing Gal4. The Gal4 expression may be controlled by a specific promoter, or by neighboring genomic enhancers (in which case the Gal4 element functions as an enhancer trap). This bipartite system is extremely flexible, since a large collection of lines expressing Gal4 in distinct spatial and temporal patterns is available. These can be combined with any UAS element carrying a transgene, which may be a reporter gene such as *LacZ*, or a mutant gene predicted to have a dominant phenotype. One exciting possibility is to express toxin genes (such as ricin A chain) in specific cell types, to investigate the developmental consequences of ablation of particular cells.
5. *FLP–FRT.* This is also a two-component system, in which one element carries the gene encoding the *S. cerevisiae* 2 μm plasmid fragment length polymorphism (FLP) recombinase, and the other the target sequences for this enzyme (FRT). The expression of FLP can be controlled in several ways as can the Gal4 described above. Cells in which FLP is expressed will rearrange sequences flanked by the FRT sites. Depending on the orientation of the two FRT sequences, this can be an inversion or an excision, enabling a gene between the sequences to be turned on or off.
6. Elements bearing visible marker genes can be used as dominant markers for the purpose of generating chromosomal deficiencies. For example, a *w*$^-$ stock (*w* mutants have white eyes) bearing a *P*[*w*$^+$] element inserted at, for example, 96A will have normal reddish-brown eyes. Following X irradiation,

flies with this chromosome region deleted will have lost the $P[w^+]$ element, and will have white eyes. These w^- stocks can be analyzed by polytene cytogenetics to reveal which, if any, carry a chromosomal deletion.

4.3 Heterochromatin

Heterochromatin is characterized by particular staining patterns that reflect differential condensation in comparison to euchromatin. Typical characteristics include late replication and a higher level of condensation than seen for euchromatin. Typically, heterochromatin is located in pericentromeric regions, and near telomeres. Furthermore, the Y chromosome is entirely heterochromatic. Heterochromatin does not polytenize, and is not represented in the polytene chromosome maps; it forms the chromocentre, from which the polytenized chromosome arms radiate. Detailed cytological analyses of mitotic chromosomes have permitted banding maps of the heterochromatin to be constructed on the basis of differential staining patterns; such maps are of low resolution, consisting of 61 defined bands.

Sequencing the DNA corresponding to heterochromatin presents considerable difficulty because of its highly repetitive nature. For this reason, the BDGP's heterochromatic sequence remains draft quality – of the estimated 59 Mb heterochromatin (to which must be added the 41 Mb Y chromosome, which is entirely heterochromatic), an unfinished draft-quality assembly of 20.7 Mb has been produced and distributed over 2597 scaffolds. Nevertheless, several conclusions may be drawn.

Some 297 protein-coding genes have been identified within heterochromatin. This total includes several loci known from genetic analyses to map within heterochromatin. Several genes that do not encode proteins have been identified; these include 5.8S, 2S, 18S, and 28S rRNA genes.

The general organization of heterochromatic DNA is in blocks of approximately 20 kb to 1 Mb consisting of satellite DNA, separated by sections of between 5 and 50 kb of more complex sequences that contain a high density of transposable elements.

4.4 Long-range Genome Structure

That the structure of the *Drosophila* genome involves long-range interactions is in no doubt, as clearly indicated by genetic phenomena, such as transvection, in which regulatory interactions between homologous chromosomes are revealed. One of the outcomes of the *Drosophila* genome sequence was the ability to examine the transcriptional activity of the whole genome with reference to specific treatments or biological processes, by microarray studies. Analyses of several microarray experiments encompassing over 80 experimental conditions has revealed that there appears to be considerable clustering of genes which share expression profiles.

Over 20% of the *Drosophila* genes surveyed appeared to be clustered in groups of 10 to 30 genes with similar expression patterns. This is likely to reflect a regulation at the level of chromatin structure. However, there appeared to be no correlation with the banding pattern of polytene chromosomes, or with

sites of known attachment to the nuclear scaffold.

5 Genetic Analysis in *Drosophila*

Despite the availability of the complete genome sequence, genetic analytical techniques remain very important. Many of the genes identified in the genome have no known mutant alleles. Examination of mutant phenotype, often in combination with mutation of other genes, has the potential to reveal their biological function.

5.1 Mutagenesis

A typical genetic screen for mutations, in this case autosomal recessive lethals, is shown in Fig. 5. A large variety of mutagens are available, which can differ widely in the nature of the lesions produced. For example, ethylmethanesulphonate (EMS), administered in the food, causes predominantly single base pair changes, whereas X rays induce chromosomal deletions and other rearrangements. The use of transposable elements as mutagens is described in Sect. 4.1.

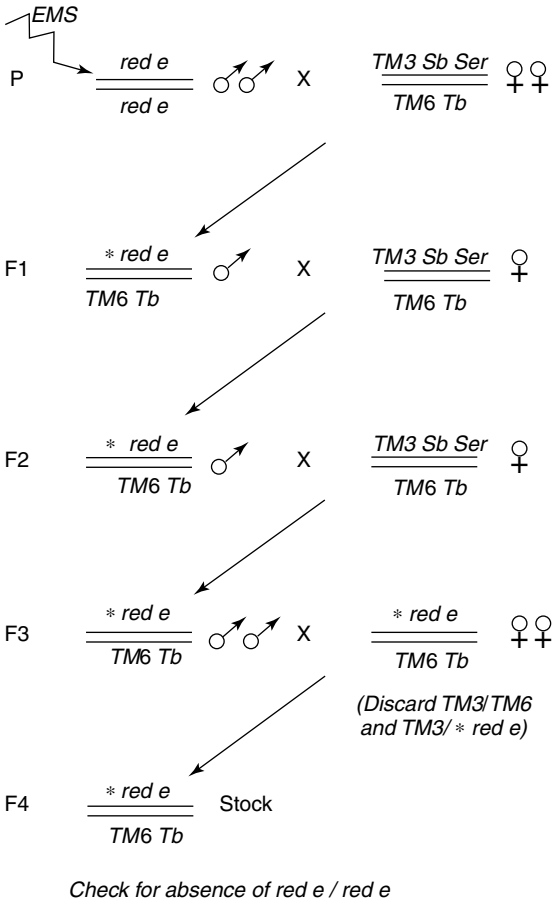

Fig. 5 Mutagenesis scheme. This scheme is designed to recover autosomal recessive lethal mutations. With minor modification, however, other types of phenotype may be screened for. Full descriptions of marker mutations and balancer chromosomes can be found in *The Genome of Drosophila melanogaster*. All females in crosses are virgin. The markers in this figure are: *red*: red malpighian tubules (wild-type tubules are whitish, this recessive mutation also results in brown eyes in the adult); *ebony* (*e*): adult has black body, recessive; *Stubble* (*Sb*): dominant mutation affecting adult bristle morphology; *Serrate* (*Ser*): dominant mutation causing serrated wing margins; *Tubby* (*Tb*): dominant mutation causing tubby larvae and adults, but more easily scored in larvae. The mutagenized chromosome is indicated by an asterisk.

Male flies are treated with mutagen, and mated *en masse* to virgin females heterozygous for two balancer chromosomes. All subsequent matings are single-pair matings, again with virgin females. The target chromosome is marked with recessive markers, to facilitate later genetic manipulations (the mutagenized chromosome is labeled with an asterisk in subsequent crosses in Fig. 5). Note that the F1 and F2 crosses are identical – this is necessary when the mutagen, such as EMS, causes lesions requiring one or more cell divisions to become fixed. The F3-cross yields a balanced stock in which flies homozygous for the mutagenized chromosome (easily recognized because of the recessive markers) can be examined for the phenotype of interest. In the case of recessive lethals, this class would be absent. Balancer chromosomes have multiple inversions, which prevent recombination from occurring, and carry a recessive lethal mutation to render balancer chromosome homozygotes inviable. In general, balancer chromosomes carry a dominant marker, so they can be followed in genetic crosses. Because balancer chromosomes suppress recombination, these features will not be separated by recombination. Some X chromosome balancer chromosomes carry a female sterile mutation rather than a lethal, so that the balancer chromosome will be male viable.

Many classes of mutant phenotype can be discovered, using appropriate genetic systems, from dominant temperature-sensitive lethals, to simple visible mutations, from female sterile mutants to behavioral mutations.

5.1.1 Reverse Genetics

Often, the *Drosophila* researcher is in the position of having cloned a gene, but is without a corresponding mutant. Unlike other model organisms, there is no efficient means of targeted mutagenesis in *Drosophila*. A useful technique in this regard is to use *P* element mutagenesis as described in Sect. 4.2 and detect insertions in the gene of interest using PCR with one gene-specific primer and one *P* element specific primer.

As an alternative to PCR screening *P* element insertions, saturation mutagenesis of a chromosomal region known to include the gene of interest, and spanned by a small chromosome deficiency can be undertaken. Mutants displaying an appropriate phenotype could then be examined molecularly, to investigate whether the gene in question is mutated.

A very powerful technique of targeted mutagenesis has been developed by Golic and colleagues. It is clear that it is of general utility, but it is uncertain at the time of writing whether it will be widely adopted by the *Drosophila* research community.

5.1.2 Classes of Mutant Allele

Several classes of mutant allele may be recovered following mutagenesis. The simplest is the loss-of-function mutation, either complete (null mutation or amorph) or partial (hypomorph). Amorphs and hypomorphs are generally recessive, and can be formally distinguished by comparing their phenotypes in combination with a deficiency (see Sect. 3.3.1). Other allelic states are hypermorphs, in which there is a gain of gene function, and neomorphs, in which a novel function is acquired. Neomorphs are generally dominant alleles. Mutants of any or all classes can be recovered for a given gene, using appropriate mutagenesis protocols.

An additional complication is that an allele's phenotypic effect may be temperature-sensitive. At its extreme, this can be seen as a true conditional

mutant, in which environmental conditions can entirely suppress the mutant phenotype.

5.1.3 Position Effect Variegation

As described earlier, most genes are located within euchromatin. In comparison with euchromatin, heterochromatin has unusual properties, connected with differences in chromatin organization and composition. These properties influence gene expression. When a gene, for example *white*, is relocated by chromosome rearrangement so that it is located close to heterochromatin, its expression is affected by the heterochromation. The heterochromatin appears to ''heterochromatinize'' its neighboring euchromatin. This occurs to different extents in different clonal cell lineages within the developing organism. In the case of a *white* allele mutated by an inversion bringing it into close proximity of the centric heterochromatin, it may be active in some ommatidia of the compound eye, and inactive in others, resulting in a mottled eye with red and white facets (*white* mutants have white eyes rather than the wild-type reddish color). The *white* allele w^{m4} is an example. There are loci that display the opposite effect; an example is *light*, which maps to the pericentric heterochromatin of chromosome arm 2L: rearrangements that relocate *light* to euchromatic regions result in reduced levels of expression. Mutants that enhance or suppress PEV are known, and characterization of these genes is illuminating with respect to chromatin structure.

5.1.4 Interfering RNA

Perhaps the single most important molecular biological technique to have been developed in recent years is that of RNA interference. *Drosophila* researchers have been able to apply this new technology in several ways – firstly by injecting embryos or transfecting cultured cells with double-stranded RNA corresponding to a gene under investigation, and subsequently examining the phenotypic consequences, and secondly by generating transgenic strains, which encode a transcript suitable for genetic interference.

5.1.5 Targeted Mutagenesis

Rong and Golic published a method for targeted mutagenesis, in which *in vitro* mutated genes are inserted in the *Drosophila* genome by P-element techniques and then substituted for the wild type allele by a recombination based procedure. A detailed description of this procedure is out of the scope of this article, but can be found in the cited references. If widely adopted, this technique has great potential.

5.2 Genetic Mapping

Genetic, or recombination mapping, in *D. melanogaster* has a long history. The theoretical basis of recombination mapping was devised and implemented using *Drosophila* in 1913. The map unit, or centimorgan (cM) corresponds to one percent recombination. Over short map distances, these values are additive, but over longer distances, complications arise from multiple crossovers. Correlating the cytogenetic and recombination map positions of a number of loci has demonstrated that the recombination rate varies along the chromosome: recombination is effectively suppressed close to telomeres and centromeres. Thus, 1 cM represents a larger stretch of DNA near the telomere or centromere than in the middle of a chromosome arm.

Under normal circumstances, there is no recombination in *D. melanogaster* males. The special circumstances in which male recombination is observed include hybrid dysgenesis. Additionally, recombination in the tiny fourth chromosome does not occur, except in triploid females.

Recombination mapping is now generally undertaken as a starting point to cytological mapping, the localization of a gene on the polytene chromosome map, and its subsequent molecular cloning. The correlation between the polytene chromosome map and the recombination map permits the approximate cytogenetic map position to be determined from recombination map data. The recombination map order of loci can be important in cloning projects.

A typical scheme for mapping a recessive lethal mutation is shown in Fig. 6. The first two crosses in this scheme are carried out *en masse*, while subsequent crosses are single-pair matings. Each recombinant stock generated in this scheme can be classified on the basis of which markers are present on the recombinant chromosome, and whether the lethal is present. This permits easy assignation of the lethal to one interval between markers. Further recombination mapping may be undertaken, concentrating on that interval, to yield a more precise map position.

5.2.1 Microsatellite and RFLP Markers

Genetic mapping in *Drosophila* has rarely used microsatellites and restriction fragment length polymorphism (RFLP) markers, due to the availability of many visible markers and chromosome rearrangements, permitting the easy localization of genes to a molecularly

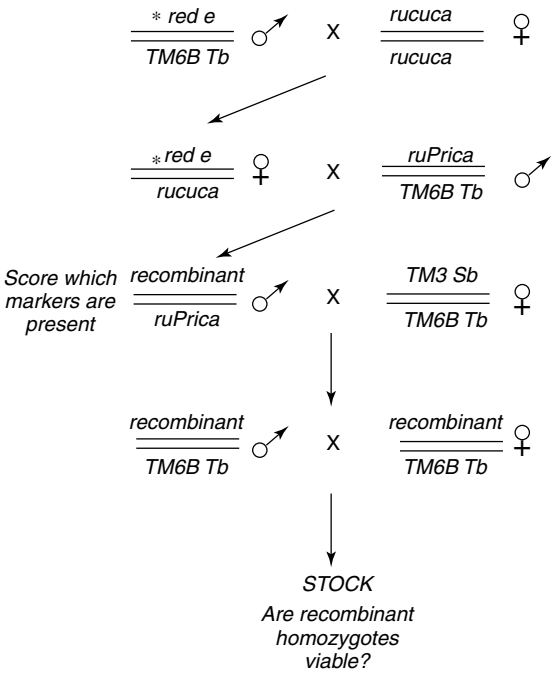

Fig. 6 *Recombination mapping scheme.* Markers are as described in the legend to Fig. 5, and are as follows. The chromosome *rucuca* is multiply marked with the following recessives: *ru* (*roughoid*: eyes are rough in appearance); *h* (*hairy*: extra hairs on wing veins); *th* (*thread*: aristae are threadlike, instead of branched); *st* (*scarlet*: adult eye is bright red); *cu* (*curled*: wings curled upwards); *sr* (*stripe*: stripe on dorsal surface of thorax); *e*; *ca* (*claret*: adult eyes are ruby red). Flies homozygous for both *st* and *ca* have orange eyes. The chromosome *ruPrica* is as *rucuca*, but in addition contains the dominant marker *Prickly* (*Pr*), which causes the adult bristles to be shortened, with twisted tips. As in Fig. 5, all females are virgin.

relevant precision. However, microsatellites and RFLPs are of central importance for recombination mapping in genetically less tractable insects, such as mosquitoes.

6 Prospects

To some extent, *Drosophila* is a late starter with respect to the development of molecular physical maps. This is undoubtedly due to having had an excellent physical map dating from the 1930s, the polytene chromosome map. It is an enduring legacy to the mapping talents of Calvin Bridges that his polytene chromosome map has continued to be relevant to researchers undertaking detailed molecular genetic studies undreamt of by the early geneticists.

Prediction of how drugs are absorbed, metabolized, distributed round the body, and excreted is increasingly important to the design of new medicines. However, it is too complex to model rigorously. Prediction algorithms are primarily based on databases of known examples, which are mined for simple rules, more complex mathematical algorithms, or rules sets. Many modeling techniques have been applied, and many ways of describing a molecule to the computer have been tested. I discuss the application of these methods for predicting whether a drug will be absorbed through the intestines, including whether it will be soluble, transported in or out by cell membrane transporters, and whether it will be metabolized, and for predicting penetration into the brain. Advanced statistical and machine learning techniques can generate good algorithms for approximating these quantities. However, predictions are not yet good enough to integrate into a ''virtual human''. The main limitation is that the algorithms need more experimental data to encompass the complexity and variability of biological systems, as well as better, more biologically relevant ways of describing the molecules to the computer.

1 Introduction

Drugs must have many properties apart from their pharmacological action and lack of toxicity if they are to be suitable as components of medicines. The ideal medicine should be easy to take, quick to act on the relevant tissue, and be required in a dosing regime that is easy for the patient to accommodate and remember, which usually means a once-a-day tablet. Whether a specific chemical can achieve this depends on whether it can be absorbed through the gut wall, once it has been absorbed, where it goes to, how long it stays there, and how it is broken down or excreted from the body. Together, these properties comprise the DMPK (drug metabolism and pharmacokinetics) or, more broadly, ADME (absorption, distribution, metabolism, and excretion) properties of the drug. Structural features of the molecules that confer suitable ADME properties are said to make a molecule ''druglike''. This article discusses the extent to which these properties can be predicted by computer software, how this is achieved, and whether such predictions can be improved to the point where they become mainstream practice in pharmaceutical discovery.

In the 1970s and 1980s, around 40% of compounds entering clinical development failed because of inappropriate pharmacokinetic parameters (although this figure is dominated by antiinfectives, whose efficacy is easy to test). This figure is substantially lower today (probably in the order of 5%) because such parameters are tested much earlier in drug discovery. However, drug discovery and development is not getting faster or cheaper. Testing ADME properties during discovery and development identifies failures earlier, but this does not seem to reduce the number of those failures and hence the time needed to replace them with more successful molecules.

The ultimate parameters in which we are interested are the integrated concentration of the drug over time after a given dose (area under curve – AUC), which provides a measure of the time for which the drug will be present in the target tissue at a therapeutically useful concentration but not at a toxic one, and the half-life, which provides an indication of how often dosing must occur to maintain a therapeutically useful concentration. (Usually, AUCs refer to blood concentration, which is taken as a substitute for tissue concentration.) The components of this are generally called ADME.

- The amount of drug taken into the animal (colloquially, ''on board''), which for any enteral route of delivery is related to its absorption.
- Its concentration, a function of how it is distributed around the tissue of the body, that is, its distribution around the body.
- How much and how fast it is removed by metabolism.
- How fast and by what route the drug and its metabolites are excreted from the body.

The four basic components of ADME are not themselves irreducible or independent and can be analyzed in terms of less complex processes, as illustrated in Fig. 1; however, as Fig. 1 suggests, there is no simple one-to-one relationship between the less complex processes and the physiological parameters that we want to know. For convenience, the whole-organism properties are usually referred

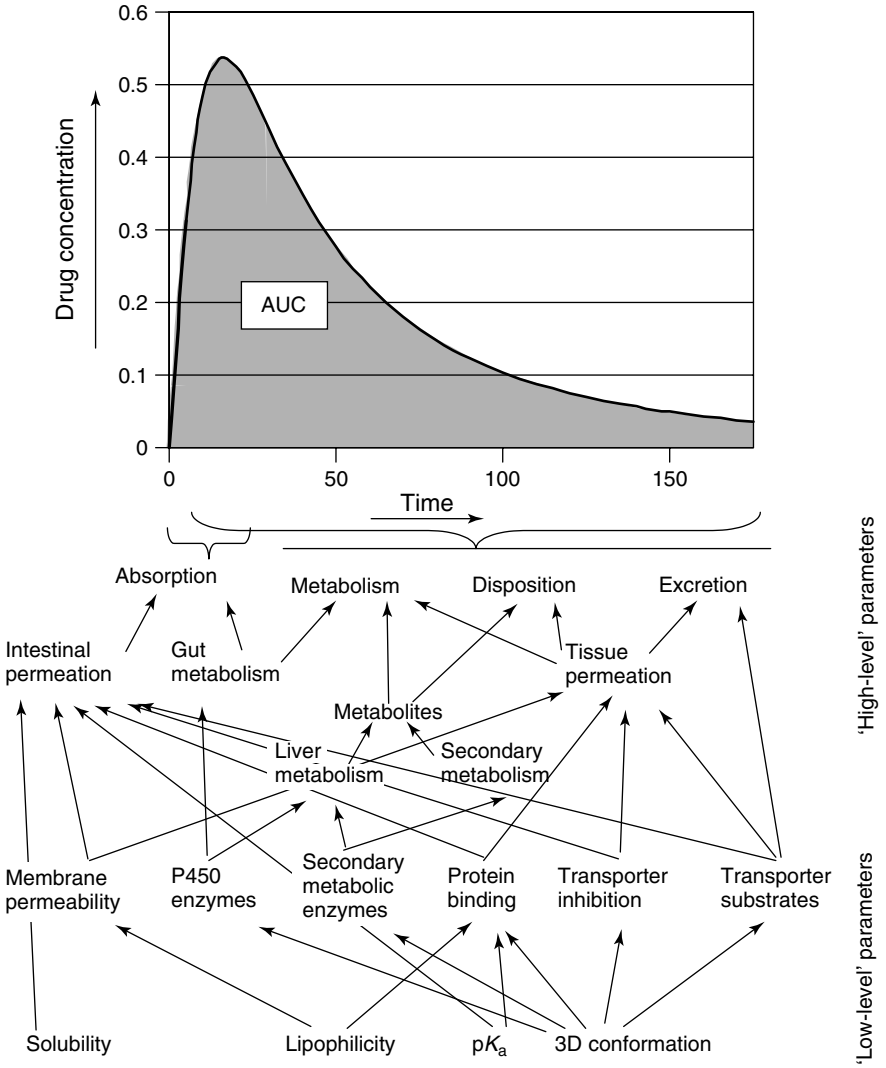

Fig. 1 Cartoon showing the concentration: time curve for a ''typical'' orally absorbed drug, the area under curve integrated time/concentration measure, and the relationship between some of its component parameters.

to as *high level* and the apparently simpler cellular and molecular properties as *low level*. The general study of how a drug's concentration changes in the body is called *pharmacokinetics*.

There are three approaches to estimating ADME properties.

Extrapolate from animal studies This is the most obvious route, and although it is not practical to continue to study compounds one at a time in animals, dosing several compounds at once into animals (cassette dosing) can extend the capabilities of animal studies substantially.

Results from rodents can be mapped onto results for man through allometric scaling algorithms, on the basis of relative mass, fluid volumes, blood flow, and other parameters.

The problem with this approach is that animal studies rarely reflect the result in man even qualitatively. It is now well known that drug metabolism is qualitatively different in the common laboratory animals and in man, with the enzyme complement differing in presence, level, and specificity: if these differences are completely characterized, then they can be corrected for, and human hepatic clearance can be predicted from scaling models. Higher-level parameters can correlate or can be apparently completely unconnected: for example, there is little correlation between overall oral bioavailability (OB) in man and in rat or dog (two commonly used model animals – see Fig. 2) due to radical differences in gut physiology, and although the fraction absorbed in monkeys and man is similar, it is more difficult from a practical point of view to test new drugs in higher primates than in human volunteers. The only appropriate model for human bioavailability as a whole is man.

Animal experiments are therefore now used to derive lower-level parameters, such as metabolism through specific enzymes, diffusion across the intestinal wall, passive diffusion across the blood–brain barrier, and so on. These are then input into a model of human physiology to provide quantitative human predictions.

Measurement of low-level properties If animal experiments are being used to measure low-level parameters, which can then be integrated into models of human physiology, can the low-level parameters not be measured directly? A recent development has been to measure ''lower-level'' properties in *in vitro* assays, and then to integrate

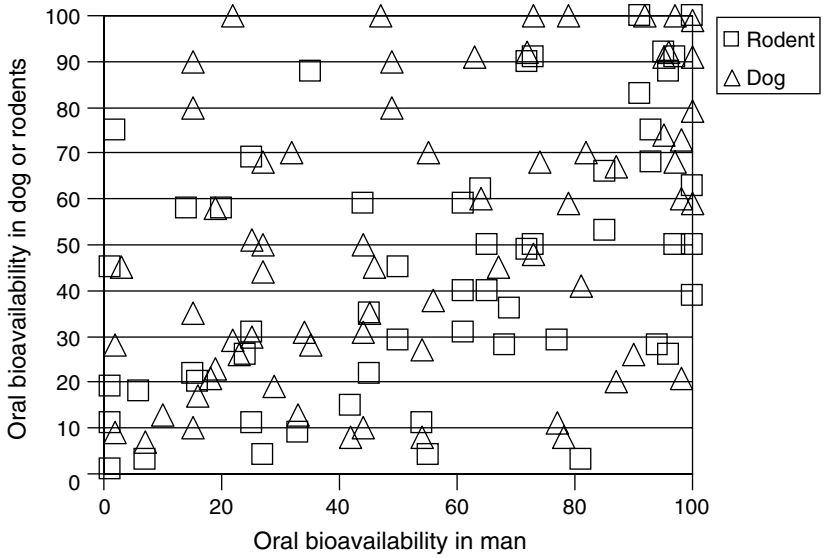

Fig. 2 Relationship between the observed oral bioavailability of individual drugs in man (*x*-axis) and in rat and dog (*y*-axis). Data from Grass and Sinko 2002.

them into an estimate of whole-organism properties. A wide range of surrogate, *in vitro* assays has been developed, many suitable for high-throughput screening (HTS) execution; some are specifically mentioned below. However, none are very satisfactory. Simplistic extrapolation from *in vitro* assays to man is very error prone, and so the lower-level results must be put into a sophisticated mathematical context to give useful predictions in man.

Prediction *in silico* The third approach therefore seeks to predict the ADME properties of molecules by computer (*in silico*) alone, or in combination with the results of HTS ADME assays. Prediction of a molecule's physiological properties before it has even been synthesized is ideal, allowing only molecules with a high chance of clinical success to be made at all.

Substantial advances have been made in determining the structure of the enzymes of drug metabolism, and this aspect of ADME will soon be amenable to ''classical'' structure-based drug-design techniques. This article therefore focuses on computational approaches to the more complex problems of absorption and distribution and the related issue of penetration of compounds across the blood–brain barrier. There is currently little work using computers to predict excretion *per se*.

2 Approaches to Modeling

The interaction of chemicals with other well-defined molecular targets can be modeled using one of the well-known molecular modeling techniques. This has limited relevance for ADME prediction. Unlike pharmacological properties, ADME properties are the result of interactions of the drug with a very large number of molecules in the body, including macromolecular complexes, the extracellular matrix, as-yet uncharacterized molecular pumps, and highly promiscuous active sites such as those for CYPs and P-gp (discussed below), whose structures are not well characterized. Even if the identity and nature of the ''target'' proteins that give rise to an ADME endpoint were known, ADME is the result of interactions with many such ''targets''; so any results from molecular modeling on single targets must be integrated to give a physiological result. Because the interactions between them are highly nonlinear, any small errors in chemical prediction can cause extremely large errors when input into the physiological model. So a variety of other approaches are used to link low-level properties of molecules with their higher-level physiological effects. These can be broadly classified as statistical or mechanistic models.

Any model that posits a mechanism and then derives a mathematical description of it to predict the outcome is mechanistic. Docking models are a molecular-level example of mechanistic models: they seek to reflect the binding of particular molecular shapes to each other in mathematics. The Michaelis–Menten equation for enzyme kinetics or the computer models for weather prediction are also mechanistic – the equations reflect what happens in the real world. In physiology, these are often called *physiological models*.

Statistical models connect an observed starting position with an observed outcome using equations that can be shown statistically to predict that outcome but without (necessarily) reflecting the ''real'' mechanism involved. Public opinion polls

are of this sort – they can accurately predict consumer preference for candy bars, holidays, and leaders without attempting to model the human mind. Statistical models are sometimes called *black-box* models: we treat the model (and the process that it is modeling) as a ''black-box'' into which we put starting conditions and from which we get answers. In mechanistic models, we can look inside the box to see the mechanics.

For ADME modeling, we can apply either type of model to high- or low-level components of the overall physiology. There are five options for combining these approaches:

I A mechanistic model could be built of the whole process on the basis of the properties of the molecules involved.
II A statistical model could be built of subprocesses on the basis of the properties of the molecules involved, and the subprocesses are then linked mechanistically into the whole process.
III Experimentally determined parameters for subprocesses could be linked into a mechanistic model of the whole process.
IV Experimental results for subprocesses could be linked into a statistical model of the whole process.
V A statistical model can be built of the whole process.

These will be referred to as Type-I to Type-V models below (this is an arbitrary classification).

As discussed, Type-I models are impractical. ADME is a complex interaction of many molecules and processes, some of which are unknown, most of which cannot be modeled accurately. So, a truly mechanistic model of how a drug interacts with a whole animal is many years in the future. Most supposed Type-I models are in fact Type-II models.

2.1 Descriptors

To apply any of the strategies discussed in the previous section, we need to describe the molecule to the computer. Molecules as drawn by chemists are convenient for human perception but not for computational analysis, so we have to identify features of the molecule that can be quantified, such as their molecular weight or the number of specific groups. Such numbers are termed *descriptors*.

A critical aspect of any modeling process is defining appropriate descriptors – successful modeling usually results from the correct combination of descriptors and modeling approach, not from either alone. In their search for new descriptors, researchers have examined ever-more complex (and hence computationally ''expensive'') ways of analyzing a molecule. This enhances knowledge of what descriptors are useful: fast approximations to the best descriptors can then be developed, resulting in a useably fast method.

The most ''mechanistic'' approach to describing molecular structure is to model the structure on the basis of our understanding of the properties of the atoms that make it up. This approach is broadly called *computational chemistry*, modeling the properties of molecules themselves. Computational methods include molecular mechanics and quantum mechanical methods.

Molecular mechanics treats atoms as points linked by bonds, and optimizes the bond length and point positions to known values of bond length and angle, and Coulombic and van der Waals' interactions

between the points. This requires accurate parameterization for the atoms and bond types involved, derived from X-ray crystal structures and spectroscopic data from known compounds, but this is not limiting for druglike molecules. Molecular mechanics is useful in ADME prediction for optimizing the likely 3D conformation of a molecule for subsequent 3D shape analysis.

Quantum mechanics calculations treat the electrons and nuclei of the molecule as independent entities. Because the Schroedinger equation (the fundamental description of any quantum mechanical system) is effectively unsolvable for molecules of more than two particles, a number of simplifications are used. These include semiempirical methods (which make a number of simplifying assumptions and then correct for the errors introduced with data from experiment), density functional models (which calculate the effects of electrons on each other in terms of a simple model of electrons in a ''gas''), and MP2, which uses a combination of simplified ground-state and excited-state wave functions to approximate the complex state in a molecule. Quantum mechanical calculations enable electron densities, dipoles, and energies of the highest-occupied or lowest-unoccupied molecular orbitals (HOMO and LUMO respectively) to be calculated, and some ADME calculations have used these parameters. Commonly used quantum-derived measures also include polarizability, polarity, and dipole moment.

The other approach that uses ''rigorous'' knowledge is the expert-based approach, where human expertise identified specific structures as having ADME relevance. This is rarely very helpful, except in the general detection of molecules as ''druglike'' (see below). There are a limited number of widely used basic drug structures, and they have some specific ADME properties that can guide the expert in their evaluation. However, as the thrust of pharmaceutical research is to generate genuinely new molecules, by definition these will not be very similar to old ones.

Many conceptually simple parameters are used in ADME modeling. For, example, molecular weight (MW) is a very simple and surprisingly useful descriptor, probably because it is mechanistically linked to diffusion kinetics and to polarizability. Other simple parameters include the following:

- *LogP*. This is the log of the partition coefficient of the molecule between water and octanol and is a measure of how lipophilic the molecule is. There are dozens of algorithms to estimate LogP. The most commonly used is CLogP, a value calculated by the Daylight software using a method of counting the number of a small number of specific, small fragments in the molecule and adding their observed LogP contributions to a set of correction factors to generate the estimate of the molecule as a whole. CLogP has effectively replaced LogP in the ADME prediction arena as a measure of the lipophilicity of a molecule.
- *LogD*. The distribution coefficient, LogD, is a partition measure corrected for the ionization of the species in water (and hence is pH sensitive).

There are a variety of closely related methods, such as the ''lipoaffinity'' measure that does not include O or N atoms, that give slightly better performance for predictions of blood–brain barrier (BBB) penetration.

- Other partition coefficients are also used, notably LogPcyc, the ratio of LogP to the partition between cyclohexane and water.

• *PSA*. Polar surface area is a measure of how much of the interactions of the molecule with the solvent are likely to involve polar groups. A molecule has no "surface" *sensu stricto*: the surface concerned is the outer van der Waals radii of the atoms and so is dependent on conformation. Thus, a full computation of PSA should involve dynamic simulation of the molecule for several tens of picoseconds and sampling all the conformers that result. Some workers have found that calculating PSA for a single (unstrained) conformer ("fast PSA") is nearly as accurate and works as well as full dynamic PSA for ADME calculations.

These are descriptors of the whole molecule. Other commonly used descriptors seek to characterize the presence of specific chemical structures in the molecule. Looking for the presence of one chemical group on its own is rarely very useful for ADME prediction, although it is a powerful method for eliminating compounds that are toxic or reactive, and is often used as an initial filter to remove such compounds automatically from large, automatically generated libraries of synthetic candidates (for example, as implemented in Vertex' REOS software – Rapid Elimination Of Swill).

While single fragments or groups are not very informative, collections of them taken together can be more useful. Molecules can be characterized by an array of descriptors relating to the presence of many different fragment types. For ADME prediction, the presence of several types of groups is counted and the counts combined. Counting methods can count any of

- atoms;
- atoms in a chemical context (thus, for example, distinguishing carbon sp^2 or sp^3 hybridized contexts ("single" or "double" bonded), carbonyl, amide, and so on);
- bond types;
- simple groups defined by connectivity (i.e. which atoms are connected to which, without regard for their spatial arrangement, also sometimes called *topological descriptors*), as is done by the software developed by Amedis Pharmaceuticals;
- known chemical groups (phenyl, pyridyl, indole, or more complex groups such as β-lactam and benzodiazepine).

The last two of these categories – counting topological fragments and known chemical groups – are known as key-based approaches. They produce a long string, called a *key* or *fingerprint*, where each bit represents whether a specific fragment is present or absent from a molecule. The fingerprints of different molecules can then be compared very quickly and the presence of specific subfragments determined. Fingerprint-based methods have been found to be generally better as a basis for searching databases of molecules with associated pharmacokinetic data than whole-molecule descriptors (i.e. molecules with similar fingerprints are more likely to have similar pharmacokinetic properties), which has encouraged their use in ADME modeling.

Approaches based on counting fragments and molecular groups were pioneered by CASE and MultiCASE, initially applied to toxicity prediction. The fragments need not be what a chemist would consider a distinct portion of a molecule but can be defined solely by the fact that the atoms in it are connected (see examples in Fig. 3.) Amedis Pharmaceuticals and Topliss et al. are unusual in relying almost exclusively on counting descriptors,

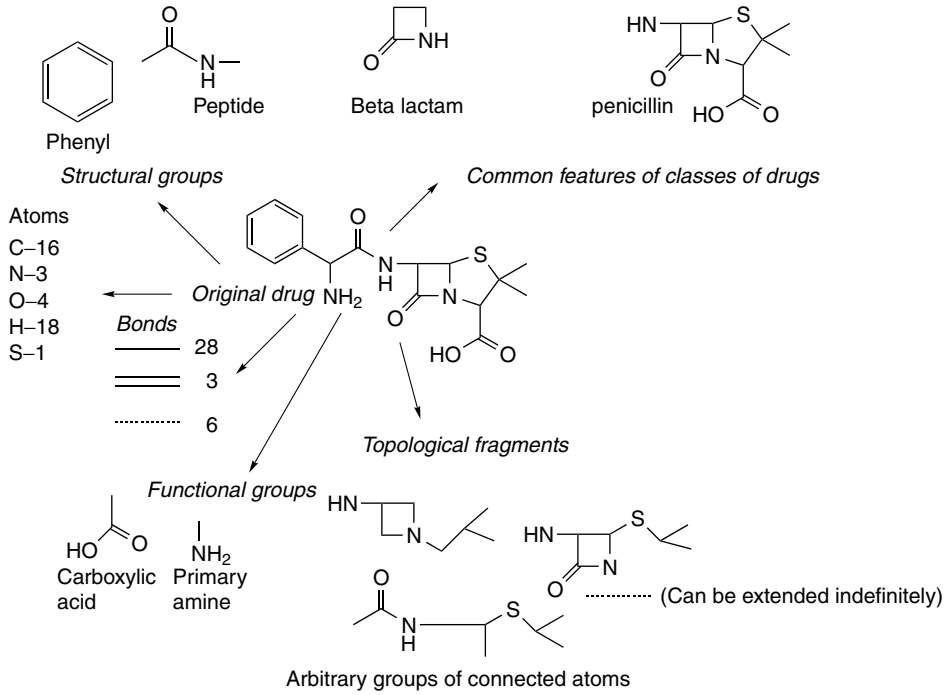

Fig. 3 Atoms, functional groups, fragments. Illustration of the types of way that a single drug structure (center) can be decomposed into (clockwise from top left) recognized chemical fragments, counts of atoms or bond types, groups with specific chemical functionality, topological fragments (groups of atoms that are connected in the original molecule, but which do not confer any special chemical significance), and fragments that are characteristic of drug classes.

together with highly nonlinear modeling methods, for ADME prediction.

If a ''fragment'' is not intuitively obvious, then how do you define what a fragment is? There are hundreds of ways of conceptually fragmenting a molecule, and even automated methods can give different results depending, for example, on whether phenyl rings are coded as bonded with true aromatic bonds or a Kekule structure. In practice, then, fragmentation is part of a specific modeling process, and the final algorithm must define what the fragment is and how to look for it in a molecule.

Counts can be combined into connectivity indices, which attempt to capture the ''style'' of the molecule – extended or compact, with or without multiple ring systems, and so on. A simple shape index can count the fraction of atoms connected to others (other than hydrogen) by one, two, or three bonds. Other more complex, information theory–derived measures measure the ''randomness'' with which the components of the molecules are assembled. All these are very rapid to compute and are based on 2D structure only.

A related and commonly used descriptor is the electrotopological state index computed by Molconn-Z. This combines a topological state index (which is a measure of the connectivity of the molecule)

with terms for electronic interactions of the atoms. Each atom type is assigned a valence electronegativity, and this affects connected atoms to an extent diminished by distance.

CLogP (and many other LogP algorithms) and PSA calculations are fragment-based methods. For CLogP, the algorithm contains a database of fragments and their contributions to LogP. CLogP adds the contribution to LogP from a small number of basic fragments, derived from measurements, and then applies correction factors related to other structural features.

Related to the presence or absence of specific groups is the idea of chemical similarity. This also describes a molecule, but in terms of how similar it is to another molecule. This is usually achieved by a scoring matrix, where each of the identified groups in two molecules is compared, and the match is the number of co-occurring groups divided by the total number of groups. The Tanimoto coefficient is one such similarity measure.

A related idea is that of ''chemical space''–plotting molecules according to chemical characteristics in a space in which the dimensions are the descriptors of the molecules. Neighbouring molecules in chemical space are more similar than distant ones. Many statistical methods discussed below seek to partition molecules in chemical space into groups that reflect ADME properties: whether this works depends on what the dimensions of the space are, that is what the descriptors are.

Such simplistic models are not widely used in pharmacological structure–activity relationships (SAR) because (apart from computational chemical indices such as dipole moment) they do not capture the 3D shape of the molecule, which is clearly important for its interaction with a receptor. For ADME properties, 3D SAR has been found to be generally less useful. However, some 3D descriptor sets have been successfully applied. Ekins et al. have done a number of studies using the CoMFA technique implemented in Sybyl. In CoMFA (comparative molecular field analysis), the surface features of a molecule in space are determined by placing it on a grid and then imagining that a test atom was at each point of that grid, and calculating the steric and electrostatic interactions between the test atom and the molecule. The result is a series of numbers that describe key aspects of the molecule's shape and electrostatic characteristics. Other simpler calculations look at aspects of the molecule such as ''shadow area'' (the maximum area of shadow a model of the molecule would cast on a plane as it rotates) and ellipsoidal parameters (how far it is from spherical).

These are all quite well established methods, and no new ''ADME-specific'' descriptors have been developed for some years. There are indications that a ''biological similarity score'' – scoring how similar a molecule is to the aggregate of all small molecules in the body – might be valuable: however, no robust test on this has been performed yet.

Many of these descriptor types are calculated by industrial or commercial programs. A selection of the more specialist programs used in ADME descriptor generation and modeling are listed in Fig. 4. ''Standard'' descriptors such as PSA, molecular mechanical descriptors, and molecular conformation are calculated by all professional molecular modeling packages.

2.2 Approaches to Building Models

A mathematical model links a description of the molecule – a list of descriptors – to the endpoint. As discussed, there are two general types of model, mechanistic and statistical. To create either, the form of the equation must be defined, and then the parameters in the equation given specific numerical values. For mechanistic models, the form is predefined and the "only" problem is to parameterize it so that it gives the correct numerical result. For statistical models, the form of the equation must often be discovered as well.

2.2.1 Types of Models: Mechanistic Models

Type-III models (purely mechanistic models based on measured values of low-level parameters) are well known. For this to be deemed truly mechanistic, the model must accurately reflect the mechanism (not just the performance) of the *in vivo* situation.

These can include single-parameter models where one *in vitro* surrogate assay measurement is correlated with an observed *in vivo* effect. An example is the widespread use of the CaCo-2 colon carcinoma cell line as a model for intestinal absorption. More complex Type-III models seek to take low-level pharmacokinetic parameters measured in animals and *in vitro* and predict the human pharmacokinetics from them, or take human data from one dose and extrapolate it to other doses or other patient groups: this is the conventional development of a pharmacokinetic model for a drug. Such models can consist of a set of differential equations that describe the rate of change of the system or a simulation of the system.

The rate of change of compound concentration in these models depends on many things – apart from the starting concentration of compounds, these can include physiological conditions, rates of bulk flow, surface areas and enzyme activities, all of which may themselves change. The set of rate equations can therefore be very complex and not always amenable to formal algebraic solution. It is common therefore to solve them by simulation – taking the starting position of the system, calculating the rate of change on the basis of that starting position for all the components, making those changes for a very small time step (milliseconds in the case of physiology, femtoseconds in the case of molecular modeling), and then recalculating the conditions of the whole system by adding those changes to the starting conditions. Such simulations can, if necessary, include the fact that molecules are discrete things, and cannot be divided, so the rate of flux through a channel can be one molecule or two molecules per time step but not 1.5 molecules. Such modeling can be by Monte Carlo simulation, where the starting conditions are varied at random according to known variation in the inputs to what is being modeled – thus one run might assume the patient was 67 kg in mass, then next that they were 75, the next 82, and so on. A succession of such runs, producing different outputs, will give a measure of the range of predicted results as well as the average.

Clinical trials design software performs a similar function, designing trials that will optimize the information arising from a clinical trial based on prior knowledge of ADME properties. This is amply discussed in standard pharmacology textbooks and will not be mentioned further here.

How mechanistic models work depends on the mechanisms believed to be

involved. (We should note that the mechanism believed to be involved is sometimes not the correct one, but the model can work nevertheless.) By contrast, all statistical models have some common properties and fall into different classes.

2.2.2 Types of Models: Statistical Models

If we do not know what form of equation links the descriptors to the endpoint, then there are a variety of statistical approaches that can provide this for us. The result is a model that is statistically valid but does not claim to reflect the underlying mechanism of the modeled process. The modeling process must select which descriptors to use, and how to link them to provide a final answer. Often, the choice of descriptors is made by the scientist, which reduces the problem (but which assumes that the scientist has made the right choice!)

The relationship between a set of descriptors and a set of endpoints is developed using a number of examples – the training set. These can be inherently involved in the modeling process or applied by the user afterwards, approaches that are called *supervised* or *unsupervised* respectively. Supervised learning techniques, such as neural nets, develop an algorithm on the basis of information about what the "correct" answer is. Unsupervised techniques develop algorithms based on the structure of the descriptors alone.

Such statistical modeling is also called *quantitative structure–property relationship* (*QSPR*) *mapping*, a variant on quantitative structure–activity relationship (QSAR) (activity). The two are exactly the same in that the activity is a subset of all the properties that a molecule has.

QSAR is a well-established set of techniques for pharmacological targets, which identifies key aspects of the drug molecule that must be present to interact with the target protein, and hence by inference the key aspects of the target protein that interact with the drug. For ADME, modeling is not so clearly related to the structure of a protein target. However, the many tools developed for QSAR in drug pharmacology discovery have been used in QSPR discovery in ADME.

2.2.3 Problems with Modeling and Overcoming them

For complex statistical modeling problems, three types of problem are common.

- *The curse of dimensionality*. There are many inputs to a problem (in our case, as many descriptors as we can imagine) and an effectively infinite number of combinations of them. How can the method sort through them for the few that do not only match the training data but can also generalize to new, "unseen" test data? (This is also related to "overfitting".)

- *Multiple local minima*. There are many "OK" solutions to a problem but few very good ones – however, it is usually not possible to adapt many of the OK ones to be a very good one. So how do you avoid the algorithm from being trapped in an "OK" solution, a local minimum in the solution space?

- *Overfitting*. A relationship between any number of descriptors and an endpoint can be derived with enough effort, but usually such a solution will be specific for those examples and will not apply more generally – it will not "generalize". How can overfitting and lack of generalization be traded off against modeling power?

There are many statistical techniques that can be used successfully to overcome these problems and match ADME data to molecular descriptors. This article will not review them all, except to mention that simple

nonlinear mapping methods have been very widely used and are often as effective as very sophisticated techniques. However, six types of more advanced techniques are widely used in the ADME research literature and will be summarized here.

Two well-known linear statistical techniques, partial least squares (PLS) and principal components analysis (PCA), have been widely applied to ADME datasets.

PLS (partial least squares) assumes that the endpoint is a linear function of the descriptors and adjusts constants in that equation to minimize the square of the differences between predicted and actual values. Simple versions of it are commonly implemented in spreadsheet and other statistical programs to provide ''lines of best fit''.

PCA (principal components analysis) performs a similar task. It plots the distribution of molecules in chemical space and then rotates the axes of that space so that as much as possible of the variability lies in the first dimension, as much as possible of the remaining variability lies in the second dimension, and so on. The new axes are called *principal components* and are linear combinations of the original axes. This then is a method of transforming the original descriptions of the molecule to focus the variability present in the original descriptions of the molecule into a smaller number of descriptions. We then observe whether the variability in the resulting reduced space is related to differences in biological response (i.e. whether there are simple shapes that we can draw in the transformed space to cleanly separate ''actives'' from ''inactives'').

2.2.4 Nonlinear and ''Artificial Intelligence'' Approaches

A limitation of PLS and PCA is that they are linear techniques – they only discover solutions

$$\text{Solution} = \text{A}\cdot V_1 + \text{B}\cdot V_2 + \text{C}\cdot V_3. + \cdots \text{ etc}$$

where V_x are variable parameters and A, B, and C are constants. The techniques seek to find what the useful values for the constants are (if possible, determining that they should best be left as zero, i.e. that variable is not relevant). This is limiting, in that we might expect our endpoint to be dependent on products of parameters, powers of parameters, or other nonlinear functions. Nonlinear techniques could produce solutions of the sort

$$\begin{aligned}\text{Solution} = {} & \text{A}_1\cdot V_1 + \text{A}_2\cdot V_1^2 + \text{A}_3\cdot V_1^3 \\ & + \text{A}_4\cdot V_1^4 + \cdots + \text{B}_1\cdot V_2 + \text{B}_2\cdot V_2^2. \\ & + \cdots. \text{ etc.}\end{aligned}$$

While there are a limited number of possible solutions for a linear function, there is a far wider space of possible nonlinear functions. Linear techniques usually come supplied with reliable and rapid one-step methods for finding optimal solutions – with nonlinear methods, the solution techniques are invariably less reliable and more computationally expensive, so searching them thoroughly is effectively impossible. In addition, nonlinear techniques have an increased risk that any model resulting from a nonlinear framework has ''overfitted'' to the training data it was presented with. So there is a trade-off in using more complex, nonlinear techniques, balancing the power of the method to discover better solutions against the risk that they find a solution that only

fits the data we have in hand, and will not generalize.

A powerful and increasingly widely used modeling method for nonlinear modeling is support vector machines (SVM). SVMs are related to PCA, but rather than partitioning data in the chemical space (''feature space'') directly, they partition it in a feature space that is to an extent nonlinear (although all of its boundary segments are linear) related to the input data space. Using Kernel functions, this can be done quickly without doing computation in that high-dimensionality space, which is claimed to overcome the computational expense of the curse of dimensionality (although not the problem of overfitting). A variety of SVM software is available for free download, which has contributed to its rapid take-up. SVMs have been used for carcinogenicity prediction, as well as QSAR, DNA sequence analysis, and some ADME problems.

Also widely used is a set of techniques called *recursive partitioning*, which can be highly nonlinear. Here, the data set is partitioned using one variable into two sets that differ for the endpoint. Each set is then partitioned again, but the criteria for partitioning can be different for the two sets. Each of the resulting sets is then partitioned again, and so on until fairly uniform sub-subsets are found.

Neural nets are a matrix method modeled on how nerve networks work and are very effective at ''learning'' complex patterns in nonlinear problems. They have been applied to conventional QSAR problems. They are characterized by their connectivity – how many input nodes, hidden nodes, and output nodes they have. In general, nets with a large number of input or hidden nodes are very hard to ''train'' in a way that generalizes to data other than the training set, and attempting to train neural nets on very large number of input descriptors (>50) is extremely difficult.

More effective means of training neural networks include prior selection of inputs using genetic algorithms (GAs) (see below) or Monte Carlo/Hastings techniques, which overcome (to some extent) the limitation of training a net using very large descriptor sets.

Genetic algorithms have no such limitation. They ''evolve'' a solution in the computer. The problem is described to the machine in numbers (as with other techniques), and the computer generates a solution through a process analogous to natural evolution: a number of possible solutions are generated, tested for their effectiveness at predicting known answers, and the best are retained, recombined, and ''mutated'' to generate new solutions, which are then tested again, and so on. While this process is very simple in concept, there are many parameters that need to be optimized for its application to a specific problem, including the size and structure of the population of problems, the nature and relative frequency of the genetic operators (mutation and/or recombination), how the fitness function operates, and the overall form of the solution. A type of GA called *genetic programing* (GP) overcomes this by evolving the form of the solution as well as its parameters, but at the cost of requiring yet further optimization parameters to be specified. GAs are particularly efficient at exploring enormous ''problem spaces'', where the number of parameters to the solution is huge and hence the ability of conventional statistical methods to explore them all is very limited. However, their application to life sciences has been curiously limited. They have been applied to molecular conformation analysis, ligand docking, and *de*

novo structure design (where a new structure is ''evolved'' to fit the criterion that it fits a known pharmacophore or docking site).

GAs have been used in pharmacophore mapping and in ''evolving'' new compounds to fit a known target site. Their use in ADME prediction is more restricted to a genetic algorithm for generating pharmacophores included in the Cerius2 software, some isolated research ''demonstrations'', and the application of GPs to ADME prediction by Amedis Pharmaceuticals.

Both ANNs (artificial neural nets) and GAs are often called *black-box* methods, methods that produce a solution, but the form of that solution and the method by which it was produced is opaque to the user. Hybrid forms, where a GA is used to pick the variables used to input into an ANN, are also known.

Complex, nonlinear methods such as GA have a termination problem – how do you know when the solution you have found is good enough? Usually, this is done by reference to a test set; however, this has statistical problems that are discussed below.

2.3 The Problem of Data

With the exception of *ab initio* quantum chemical calculations, all modeling of the properties of potential drug molecules is based on data about the modeled parameter from other drug molecules, and as rigorous *ab initio* quantum calculation of the many-particle body that is a drug molecule is impossible, this means that all modeling is based on experimental data. The importance of good data on which to base models cannot therefore be overemphasized. What that data is depends on the type of model being developed.

If the model is based on fundamental chemical properties (a chemically mechanistic model in the terminology above), then the data are the modeling parameters for the chemical modeling software, and as this is independent of the biological context of the chemical, it is also independent of any requirement for biological data. However, few of the modeling results below are like this: nearly all are developed by reference to actual biological results. Even such highly mechanistic models as the Abraham model of intestinal absorption have to be ''parameterized'' (i.e. have the constants in the equation adjusted) by reference to actual biological data. So real experimental measures of the parameters that we want to model are critical.

This is a problem because these data are scarce, because they are expensive in time and resources to acquire – which is why we want to model those endpoints instead of measuring them. Existing datasets are usually biased in terms of the chemicals examined and the range of endpoints that are found. For example, very few measurements of OB include drugs with very low OB, but it is precisely the modeling of very low OB compounds (so that they can be avoided) that we are interested in. Data is also always ''noisy'', in part because the difficulty in accurate measurements of complex ADME endpoints introduces experimental error, in part because the variation in biological systems introduces real variability, and in part because different groups measure complex parameters in different ways, with different results. The result can be enormous ranges in apparently quantitative measurements (see Fig. 5). In addition, compilation and transcription of the data is itself error prone,

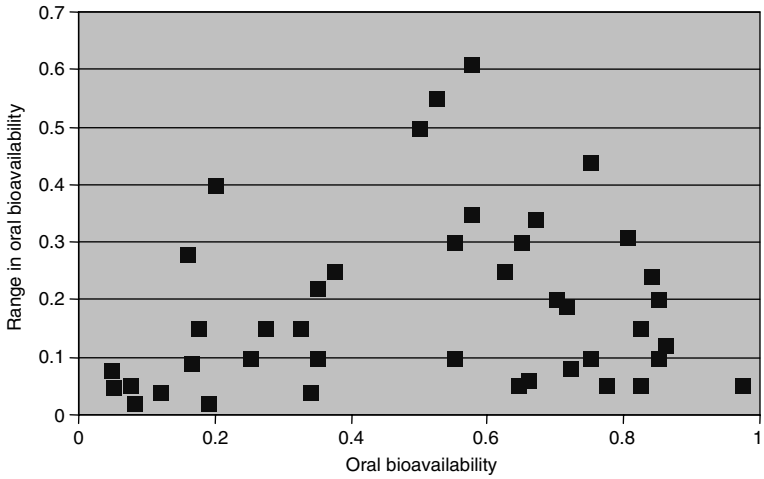

Fig. 5 Plot of the range of reported human oral bioavailability values for 50 drugs for which a range is described. *x*-axis – OB values. *y*-axis – range in OB values. Data from Goodman and Gilman, and Dollery.

so databases can be even noisier than the data from which they are derived. White and Sverlenko found several errors and a number of duplications of data in apparently carefully compiled data sets for blood–brain barrier penetration, which had been widely used in literature studies.

Thus, a major part of any modeling program is actually compiling the necessary data, and as a result, the databases themselves are valuable. Most ADME modeling results use previously compiled data, often published in the literature, as the cost of generating enough data within one research program would be prohibitive. An exception is the metabolism prediction work done by Cyptotex, who run their own screens to generate consistent data for CYP metabolism and CaCo-2 permeation. This will not be discussed further as there is no ''magic technique'' for getting good quality data by experiment or literature; it is a matter of effort and scientific rigor.

2.3.1 Datasets and Statistical Reliability

All the statistical modeling techniques seek to fit a mathematical model to a set of examples collected, as above. However, we do not actually want an equation that represents the data we already know – we want one that predicts the desired endpoint for a compound we do not know about. The model must be able to generalize to new compounds. As mentioned above, it is easy to use powerful statistical matching methods to fit a complex equation to what amounts to a set of points on a graph; however, there is a point when the equation becomes overfitted – it fits the known data extremely well but does not generalize.

To avoid this, it is essential to split the data into at least two sets – a training set, which is used to optimize the algorithm, and a test set, which is not used as part of the training process but which is kept separate until training is over, when it is used to see whether the resulting algorithm can predict results for molecules that were not used in its construction.

Division into training and test sets can be done by any method, providing that method is not related to the training itself.

Ideally, the training and test sets should be of similar size; however, when data is limited, it is common practice to make the training set larger than the test set. The problem with this is that, if the result is poor, it can be blamed on the fact that the small test set happens to include an unrepresentative collection of molecules; the temptation is then to select a new test set and train again. This is invalid, as the way you select the test set is influenced by the training result, that is, it is not actually independent. A similar invalidity arises when ''outliers'' are identified from the results of training, excluded, and then training performed again.

An only partially valid approach is the ''leave-one-out'' approach, where one molecule is left out of the training set, training performed, and the match of the one excluded molecule is determined, then another left out and the process repeated. Overall, there are no molecules that can be said to be independent of the training process, although for each test, the ''test set of one'' is independent. Such ''leave-one-out'' statistics are common in ADME prediction as they allow maximal use of the sparse data sets in training.

Evolutionary techniques have an additional problem of when to stop, as mentioned. Termination can be directed by performance against the test set – when the models being generated stop generalizing, you know you have gone too far. However, this means that you are using the test set to control how you do the modeling – it is not truly independent. So for nonlinear, data-driven methods, a third set of data is needed that is not involved in the training process at all, with which to validate that the result produced is general. It is rare for any ADME studies to use this level of rigor, because there is too little data to split it into three data sets.

A related concept is shuffling the observed values between different molecules and seeing if the training algorithm still claims to a good model. If the target values that the method is predicting are actually predicted by the molecular structure, then the shuffled results should give no training. This is used more to validate that the training method is producing meaningful answers than to confirm the generality of one of those answers.

2.4 Conclusions on Modeling

Modeling, therefore, is a balance between the amount of data available, the relevance of the descriptors, and the power of the modeling technology. Enhancing the modeling technology power has risks as well as benefits, so it is always preferable to find more data (if it is available) or use more relevant descriptors (if you can invent them). A strategy for developing ADME models, or indeed any other statistical model, is to start with simple modeling techniques and move to the more complex ones only when the simple ones have proven inadequate.

3 Mode of Deployment

These technologies are applied in one of three broad ways. In all cases, computer-based approaches are used to support decision-making, rather as decision methods on their own.

- *For library selection*. A decision that the medicinal chemist has to make early in the lead development phase of

chemistry is which ''lead'' to use as the basis for development of focused libraries of compounds for further testing and development of a SAR. Predictive ADME programs can be used against all the possible compounds in a ''virtual library'' to prioritize libraries for the future medicinal properties of any lead that will emerge from them. This requires only rough categorization of individual compounds to be effective.

- *For synthesis selection*. A subsequent step to this, having chosen a library scaffold, is to select the subset of the possible library that will be synthesized. This requires accurate classification or semiquantitative prediction of endpoints.

- *For compound selection*. When faced with a small number of candidates for preclinical workup, fully quantitative models can be used to prioritize which to take into this expensive and time-consuming stage of development.

The majority of users at the start of the twenty-first century see predictive ADME in the first of these roles – as a coarse filter in early chemical design. This means calculating results for thousands or millions of molecules.

This has important implications for the speed of the model. We must distinguish between generating the model (which can take months or years) and delivering the model. A model delivered into the hands of chemists must be able to help their decision-making process and so must be able to process all the molecules that they want to process overnight or faster (and ideally as fast as they can generate them). The limit on algorithm speed is usually descriptor calculation (as the algorithms themselves simply combine the descriptors in simple equations that can be coded in a few hundred instructions or less). So there is a premium on descriptors that are fast to calculate. Thus, simple counts of chemical groups based on 2D structures are much to be preferred to rigorous quantum chemical calculations or computation of all possible conformers of a molecule.

In all cases, it is helpful if the algorithm being used is interpretable, so that the output of the algorithm is easy to relate to features of the molecule that a chemist can then alter. In this respect, PSA is an excellent parameter – to a good approximation, it is just the sum of the nonbonded ''surface'' of the N and O atoms and the hydrogens attached to them, so a result that derives from an adverse PSA measure can be changed by ''just'' altering those aspects of the molecule's chemistry. Few other descriptors are that simple, and when they are, the algorithms that integrate them into an ADME prediction are so nonintuitive that the value of the descriptor transparency is lost.

In practice, a completely opaque black-box algorithm can still be used as an *in silico* experiment, into which the chemist puts new candidate designs and from which he/she obtains estimates of how those designs will perform in reality.

4 Accuracy

Computer predictions need to be accurate, and, equally importantly, we need to know how accurate they are so that we can weight decisions made on the prediction appropriately. In fact, ADME prediction is already as accurate at predicting the human result as *in vitro* surrogate assays (see, for example, Boobis et al., 2002).

However, more is expected of it, as it is being compared not to a chemist's intuition but to actual experimental data, which by definition are 100% accurate even when, as is often the case with animal models of human ADME, they are misleading.

Accuracy is generally described by an R^2 (correlation) measure for quantitative measures, a percentage accuracy for qualitative ones (here designated C_a), or Spearman's rank coefficient, which determines the extent to which the compounds are sorted into the correct order, even if the absolute values for the predicted parameter are not accurate. (Rank ordering is almost as good as absolute accuracy for some applications, where the objective is to find the best N of a set of molecules.) Because many models are data-driven, it is possible to overfit them so that R^2 is very close to 1; however, these models perform very poorly on new molecules that are not part of their training set. A more useful measure is therefore the square correlation with a set of molecules that has not been involved in the training, which is usually designated Q^2. C_a is calculated for an independent test set, not the training set. (We note above that this needs to be an *independent* test set, not a test set that has actually been involved in the training process.)

To compare different algorithms, they must be applied to the same set of molecules, because accuracy also implies accuracy in a specific chemical space, not across all possible chemicals – this is rarely done.

All models divide into local, and general or global models. The former apply only to molecules of a particular chemical type, formally ones that fall into a specific volume of chemical space. Global models claim to predict results for all molecules. In reality, they too are limited, in this context to all druglike molecules: to expect a model meant to predict the properties of carbon-based, druglike molecules to generalize to, say, uranium hexafluoride is unreasonable. Thus, it is important to state the chemical space over which a model is valid. Too often this is not done until the model is found to fail to predict known results for a new type of molecule.

An indication that a supposedly global model is actually a local one is when its performance is substantially worse on a new set of molecules, even if they are apparently broadly the same as the set for which it was developed. This is a common observation: the results for several OB models reported by Bains et al. were over 90% accurate for the molecules used in this study, but this fell to 80% for both their model and the other models used as comparisons in the study when run on a different set of molecules. It is not surprising that no model is truly global – as mentioned above, non-druglike molecules are likely to fall outside the chemical space of a model developed for drugs. However, we should note that even within the chemical space of ''druglike'' molecules, there are many domains, and most models do not address them all equally well.

A related fact is that no model is perfect. Biology is full of nonlinearities and exceptions. For example, all prediction systems for OB and metabolism predict that cyclosporin and erythromycin will be almost completely orally unavailable and rapidly metabolized if injected (unless these systems encapsulate specific ''exception rules'' about these drugs). In fact, both are well absorbed and have usefully long serum half-lives. It may be that the increasing sophistication of medicinal chemistry leads to this type of highly functionalized molecule becoming common in

synthetic drug discovery as well as in ''natural products'', in which case many of the models discussed below will have to be rebuilt. So models will have to either include sufficient understanding of biology to predict when complex molecules such as erythromycin will generate ''exceptions'' or have explicit rules in them to deal with them *ad hoc*. At the moment, there is insufficient ADME data available to allow either of these solutions to be implemented; exceptional molecules just give the ''wrong'' answer.

With this armoury of techniques available, what models of ADME properties have been built? I will concentrate on models that predict absorption (oral bioavailability) and distribution. Models of metabolism (especially hepatic metabolism) are in flux, and, with the availability of X-ray structures for the CYP enzymes, will soon be put on a more rigorous, mechanistic footing, although they are mentioned below for their contribution to OB. Excretion is still not modeled to any significant extent: it is measured in animals and then extrapolated to man.

5 Oral Bioavailability

Oral bioavailability is defined by the European Committee for Proprietary Medicinal Products (CPMP) as the extent and the rate at which a substance or its active moiety is delivered from a pharmaceutical (dose) form and becomes available in the general circulation. A major target for modeling is oral bioavailability, the extent to which an orally administered drug ends up in the systemic circulation. All types of models (except Type-I) have been developed to predict oral bioavailability.

The barrier between the contents of the gut and the systemic bloodstream is one of the most critical in the body. Animals are exposed to many potentially dangerous agents on their skin, exposed mucosae, and in their lungs, but only in the gut do they deliberately take in potentially poisonous materials in concentrated form, and then treat them so as to release all their toxic contents.

The barrier is in two parts. The cells of the intestinal epithelium form a barrier through which few molecules can penetrate. Those that do are liable to metabolism in those cells. Molecules passing through the epithelium into the blood are collected into the hepatic portal vein that flows to the liver, which contains a more extensive set of xenobiotic metabolizing enzymes. Only molecules that pass both barriers accumulate in the blood. Overall OB is the combined effect of how rapidly, and in what concentration, a drug is delivered to the intestine, transit time in the intestine, dissolution rates and extents, transfer across the gut wall, metabolism in the gut wall, and metabolism in the liver (also called *first-pass metabolism*).

Oral bioavailability is operationally defined as the ratio of the integrated plasma concentration (AUC) of a drug after an oral dose to that after intravenous injection. However, this can be hard to determine as it requires the fate of all the drug that is tracked – this means detecting unabsorbed drug in urine and faeces, and all the metabolites of the drug in blood, urine, faeces, and tissue. It can also be corrected for solubility effects if the solubility in the conditions of the intestine are known. However, these corrections are complex and time-consuming, so usually the OB is calculated simply from the plasma AUC for the ''parent'' drug.

5.1 Simple Rules for OB

Many studies have sought to find simple Type-V models that are based on a few rules or molecular motifs to predict oral bioavailability. By far, the most generally used is Lipinski's Rule of Five. Lipinski developed four ''rules'', which are used as a classificatory model of whether a compound will have ''good'' OB or not. They were derived essentially by inspection of 2,287 compounds with United States Adopted Name (USAN) or International Non-proprietary Name (INN) designations (as opposed to just chemical names), because such names are usually assigned prior to entry into phase II clinical trials, meaning that these compounds had satisfactorily completed phase I clinical trials, which evaluate safe dosage levels and include assessments of ADME/toxicity properties.

The rules are as follows:

1. ClogP < 5
2. Molecular weight < 500
3. H-bond donors < 5
4. H-bond acceptors < 10

The first two are primarily associated with membrane and aqueous solubility. The second two are independently predictive of OB. If a compound breaks any two (or more) of these rules, it has a low chance of being orally bioavailable.

These have the enormous advantage that they are all easy to compute, and all of them have immediate and obvious interpretations for the medicinal chemist. Subsequent extensions have included a maximum number (usually 5) for the number of rotatable bonds (NRB).

The Rule of Five remains one of the most effective *in silico* predictors of OB. There have been many projects to extend the Rule of Five, either enhancing its performance by including more parameters or by turning what is a rather fuzzy classifier into a quantitative estimate of OB. Generally, these have not been taken up: several extensions and optimizations of it have not proven more useful to the chemist ''at the bench'', although they are statistically more accurate. These include refinement of the definition of hydrophilicity, and quantitative equations that link LogP and hydrogen bonding to a semiquantitative estimate of OB.

To an extent, this is an effect of organizational inertia. The Rule of Five was the first popularized rule set that was (1) easy to compute, (2) interpretable in chemical terms, and (3) backed by a major pharmaceutical company (Pfizer, Lipinski's employer at the time). The Rule of Five is now widely used as a screening criterion for compounds being considered for chemical research, and in Pfizer, they are automatically checked for every compound designed. This has resulted in a reduction in average molecular mass and an increase in hydrophilicity of compounds entering synthesis, a reversal of a 20-year trend away from ''druglike'' compounds. It is the aim of many ADME prediction software projects to be as widely implemented and as successful as the Rule of Five.

Exceptions to Rule of Five occur. Some are molecules that mimic biological molecules, and hence are the subject of specific transporter systems, such as the macrolide antibiotics mentioned above. Egan et al. showed that other failures of Rule of Five, which is essentially a linear (additive) rule, could be explained by nonlinear combinations of essentially the same variables. For example, highly

lipophilic compounds are rarely soluble – adding an ionizable center would, under simplistic linear rules, make the compounds less likely to have good OB, but because they enhance solubility, they actually enhance OB. However, the number of examples of each exception is too small at the moment to build systematic models from them in their own right.

The only major extension to the simple rule sets for overall OB calculation is the use of PSA calculations in OB prediction. This is primarily a model for intestinal absorption, and not of overall OB, as discussed below. AstraZeneca have examined the role of the Lipinski descriptors in screening out compounds with poor OB, and have found that PSA and NRB are not relevant when MW and LogP filters are used. While in theory, and for a very diverse set of molecules, considering PSA and NRB enhances the accuracy of these rules, in practice, for the molecules being considered by drug discovery departments, all the information in PSA and NRB that is relevant to OB prediction is captured in the other Lipinski parameters, and specifically, a major contributor to PSA is H-bond number, which is already captured in Rule of Five.

Other group counting methods have had limited success. Counting specific chemical moieties does not lead to good prediction of compounds that are orally available, but can be used to eliminate drugs that clearly cannot be orally available but can be generated by automated chemical design programs. This allows the automatic elimination of groups such as phosphate and quaternary nitrogen from compound libraries being designed for drugs that are to be orally available.

A related, but much fuzzier, rule set is that which determines ''drug-likeness''. The idea of a ''druglike'' molecule has been alluded to above, but what exactly is it? A ''druglike'' molecule is one that a chemist would view as being similar in structure to the structure of successful drugs, and this usually reflects a combination of high intestinal absorption (IA) and low first-pass clearance. There has been less success in defining ''druglike'' in simple algorithmic terms. In general, drugs are not chemically reactive, do not contain a number of groups that are the subject of rapid metabolism (such as phenols), are rigid structures, and have no more than two or three asymmetric centers (this makes synthesis easier, and has little to do with their biology). So far, ''druglike'' has tended to be a very subjective measure and one that has not been automated in a consistent way.

5.2 Advanced Type V Models for Oral Bioavailability

Further development beyond qualitative guidelines such as the Rule of Five has required more complex mathematical models, breakdown of the problem into simpler, lower-level problems, or both. The conceptually simplest approach is to take similar datasets to that used by Lipinski and apply more sophisticated modeling tools to it.

This has been performed by several workers with modest success. Yoshida and Topliss used a variant of discriminant analysis to derive a model of overall OB that classifies compounds into one of four classes – $<$20%, 20 to 49%, 50 to 79%, and $>$80% oral bioavailability. This uses 18 descriptors, including LogD, $(\mathrm{LogD})^2$, $(\mathrm{LogD}_{\mathrm{pH=6.5}})$ to $(\mathrm{LogD}_{\mathrm{pH=7.4}})$, and occurrence of a wide range of molecular fragments such as lactam and benzodiazepine rings that classify compounds

into different classes, and groups such as primary and secondary alcohol, allylic oxidation sites, and esters that are prone to chemical or enzymatic degradation. The descriptors were selected as potentially relevant before modeling. This is a linear method, but a requirement for $(LogD)^2$ is fulfilled by including $(LogD)^2$ as an explicit descriptor. Bains et al. use GP to select an algorithm that combined topological fragment descriptors into a classification into high–low classes or the Topliss four classes. Performance was broadly similar, with the GP-derived algorithm performing slightly better and both well outperforming Lipinski. However, this is probably at the expense of globality of the models, as they rely on detecting fragments that are present in orally available drugs. This is particularly true of Topliss, who explicitly coded existing drug classes into his descriptor library. By comparison, Bains et al. used an entirely automatic technique to generate a very large molecular fragment library, from which the GP systems selected those fragments most relevant to prediction. The fragments that the GP ''selects'' are very diverse and may in fact reflect simple molecular parameters, an ''improved'' version of LogP rather than anything more subtle.

5.3 Models of Components of OB

Modeling OB as a target in its own right has had limited success, and in any case, if such a model predicts that a molecule is poorly absorbed, it is not immediately obvious what to do about it. So more attention has been paid to modeling components of OB, which can then be treated separately or integrated into a Type II model.

Widely modeled components are the physicochemistry and physiology of getting solid drug into solution in the gut, the absorption of dissolved molecule from the gut into the blood, and the clearance of the molecule from the hepatic portal blood supply by the liver before it gets to the general circulation.

5.3.1 Gut Physiology, Solubility, pK_a, and LogP

Before the drug molecule gets to the intestinal epithelium, it must get to the intestine and dissolve (not necessarily in that order). Both aspects can be modeled. Modeling gut transit times and volumes is a mature science with a substantial knowledge base. This is a problem of formulating the mechanics of the gut in mathematical terms, and while complicated, it is conceptually straightforward.

5.3.2 Solubility

Prediction of solubility is a very active area of research, reviewed recently by Livingstone. It is complex, as how much drug dissolves in the gut is a kinetic as well as a thermodynamic measure, and the rate of solution depends on particle size, crystal structure, formulation and so on, and on gut physiology.

Clearly, very low solubility will result in poor OB because the concentration of the drug in the intestine will be low and the majority will be excreted undissolved. Poor solubility (meaning a solubility such that the volume of the intestine can only dissolve a very small fraction of the required dose) can also result in very variable absorption, because the amount of drug that is taken up depends on how fast it is removed from the gut and how fast it dissolves to replace that removed, both of which depend on many variables.

Variable OB is a worse problem for the pharmaceutics scientist than constant, low OB, as it is impossible to define a dose that will accurately deliver a standard concentration to the blood.

As well as implications for absorbability, low solubility has other implications for the drug discoverer. Very low solubility in water will mean that the compound will give false results in all assay types (either because it does not go into solution, and so give uniformly negative results, or because it remains in suspension as light-scattering or fluorescent ''haze'' and produce false positives). Estimating solubility, ideally before a compound has been made, is of substantial importance.

It might seem perverse to predict solubility, when all that the scientist has to do is add some drug to water and see how much dissolves. However, even this requires the scientist to make the compound: it would be very valuable to be able to predict the solubility before a compound is even made, thus helping the scientist to decide whether it was worthwhile synthesizing it in the first place. This is the role of *in silico* methods.

There is a lot of solubility data available in the public domain, but much of it relates to small, nonpolar molecules, whose solubility properties may not be relevant to the larger drug molecules. So solubility data is limited for modeling.

For simple, uncharged molecules, aqueous solubility can be predicted on the basis of LogP, which measures the ability of the molecule to penetrate the hydrogen bond network of water. Hansch has derived the now ''classical'' solubility relationship between solubility and LogP.

$$\text{Log(Sol in water)} = 1.339\,\text{logP} + 0.978$$

which has an $R^2 = 0.874$ for small, liquid organic molecules. Where molecules have significant intermolecular attraction (charge, polarity, mass) or significant interaction with water, estimating solubility is less easy. If the melting point is known for a molecule, then this can be used as a measure of intermolecular forces of all sorts and can be included in equations for solubility. This requires experimental measurement, which, although can be done fast and on a few milligrams of material, still requires the material to be synthesized. Ran et al. generated an equation of this sort of druglike molecules with a root mean square error (RMSE) of 0.76 log units using a training set of 413 compounds. Abraham et al. apply an equation based on solution thermodynamics but based on calculated parameters (see below) to calculate solubility effectively. This solution is marketed commercially as Absolv.

Just as LogP (a solution phase parameter) can be calculated by summing the contributions of fragments of the molecule, so Klopman and Zhu have built a model from 1,168 compounds using fragment contributions to solubility, getting an R^2 of 0.95. Huuskonen has used a set of 30 topological descriptors (including 24 atom-type electrotopological state indices, two path 1 connectivity indices, a flexibility index, a number of hydrogen bond acceptors (HBA), an aromaticity indicator, and an aliphatic hydrocarbon indicator). These have been used to develop multilinear regression models on a total of 1297 molecules ($R^2 = 0.89$, $Q^2 = 0.88$) and a neural net model, which gives an impressive $R^2 = 0.94$, $Q^2 = 0.92$ (although the ''Q^2'' values derived for this work are based on ''leave-one-out'' measures rather than matching to a genuinely independent test set). MultiCASE, a fragment-based analysis system, has a module for predicting solubility on the basis of the contribution of individual fragments.

Calculations based on more complex descriptors, especially electrotopological descriptors, can also be used in this mode to obtain R^2 greater than 0.9, as can quantum calculations. However, this suffers from being a very complex model, and hence one that is hard to interpret. Other simpler neural nets perform more poorly, for example, Liu and So based on a neural net model and 7 input variables, mostly topological. The model gives $Q^2 = 0.82$.

Several of these algorithms have been implemented in commercial programs that seek to predict the aqueous solubility of organic compounds. Most do not fare well for any but very simple molecules, or molecules in a single chemical series (for example, alcohols). A widely used one in drug discovery is QikProp, which uses an eight-parameter model

$$\begin{aligned}\mathrm{Log}(S) &= 3.886 - 0.0194.SASA \\ &+ 0.514HBA + 0.578HBD + 1.343(NH) \\ &+ 1.224(CNO) - \frac{116.HBA.\sqrt{HBD}}{SASA} \\ &+ 0.182(rota) - 0.00405.WPSA\end{aligned}$$

where $SASA$ is the solvent accessible surface area, HBA and HBD are the number of hydrogen bond acceptors and donors respectively, (NH) and (CNO) are the number of amine and amide groups, *rota* is the number of rotatable bonds, and $WPSA$ is the weakly polar surface area, a subset of PSA. These parameters come up as common contributors to IA and BBB (see below), which suggests that common processes are involved in solution and biological barrier penetration, even for drugs when solution is not limiting.

However, global solubility models are possible. Pharmacia developed a model for intestinal permeability using an internal compound set, obtaining $R^2 = 0.79$ for the local chemical space but only $R^2 = 0.39$ for global performance across all their compound collections: this decline in performance is typical of the models cited above when they are applied outside their training domains. By including a representative sample of all those collections in the modeling, the same group built a PLS-based model on the basis of 24 equilibrium solubility measurements made on 1,107 compounds (a substantial investment in laboratory work), and produced a model with $R^2 = 0.92$, $Q^2 = 0.91$. This is accurate enough to provide useful quantitative predictions.

A related physicochemical measure is pK_a, which affects a drug's charge state at specific pHs and hence both its aqueous solubility and its LogP (and hence its ability to dissolve in lipid membranes). It is generally true that a fractional ionization of >10% leads to low intestinal absorption. Commercial pK_a predictors exist, but usually work only for molecules with simple, monofunctional groups, and cannot cope with the complexities of druglike molecules. It is also not clear whether the ionization state is truly relevant. Some find that computing it does not improve prediction of OB, and so, except for eliminating multiple charges (such as on the bisphosphonates, a notoriously poorly absorbed group of drugs) from consideration at all, most workers do not seek to include explicit calculation of charge state in their OB models.

5.3.3 Intestinal Absorption

Once in solution, the candidate drug has to cross the intestinal epithelium. The intestinal epithelium is a physicochemical barrier (as is the blood–brain barrier discussed below). The physical barrier

is the lipid membrane of the intestinal epithelial cells: molecules that pass easily from water into lipid and back will penetrate this readily. Thus, measures of lipophilicity and hydrophilicity (related to hydrogen-bonding potential) are often central to predictions of IA.

There are actually two mechanisms by which a drug can pass through the intestinal epithelium – transcellular (crossing the lipid membranes of the cells) and paracellular (permeating across the tight junctions between cells). Paracellular transport is slower because the area of pores is much smaller than the area of the cells; however, it has different requirements for lipophilicity and is not affected by P-glycoprotein (see below). The molecular weight cutoff for effective paracellular transport is about 300 Da. The effect is that for most drugs the transcellular route is the only one of importance, and hence the drug's IA is dominated by its lipophilicity and its ability to avoid the P-glycoprotein export pump.

Prediction of IA has been achieved using several approaches with an accuracy comparable to the accuracy of the *in vitro* permeation model based on the CaCo-2 cell line (discussed further below).

Passage across the membrane can be modeled using molecular modeling methods because, although the membrane is a complex entity containing a huge number of atoms, it is chemically relatively simple if proteins are ignored. Novartis has worked on modeling the lipid membrane by simplifying lipids into connected ellipsoidal ''atoms'' that reflect the segments of the molecule to simplify the problem. Dimeristoyl phosphatidyl choline is modeled as 11 units – choline, phosphate ester link, glycerol, two acid ester groups, and three side-chain groups per fatty acid. The distribution of a drug across this membrane is well modeled, and assuming that entry into the lipid phase is determined by bulk water concentration and exit from it is determined by the concentration in the outermost layer, this can be used to estimate the rate of crossing. This has not yet proven superior to simple numerical modeling approaches, but unlike them it is open to refinement as computational techniques improve.

Until such improvements are developed, simpler associations of molecular properties with IA remain dominant.

A major contributor to IA is the molecule's ability to diffuse across the cell membrane – highly hydrophilic molecules such as sorbitol have effectively zero IA. LogP has value for IA and OB prediction on its own, and the role of LogP in the Rule of Five reflects this.

Other measures of hydrogen-bond potential and lipophilicity have been used. PSA is a general measure of the degree to which a molecule can interact with water, and hence its hydrophilicity, and is strongly negatively correlated with IA, with a sigmoidal relationship that gives an $R^2 = 0.94$ for a small drug group, but does not fare so well for a larger group of molecules, generating a Q^2 of between 0.7 and 0.8 in several studies.

A variety of studies have compared the value of fast PSA with dynamic PSA in predicting IA. Some have found that full 3D conformer PSA is better than 2D approximations; others have found that this is not so. The differences in conclusion are probably related to minor differences in algorithms and in the biological data sets used to test them.

A PCA analysis of MolSurf outputs (a quantum chemistry program) found that one principal component made up from the number of HBD, the polarity,

the strength of hydrogen bond–accepting oxygen atoms, the hexane : water partitioning coefficient, and the number of nitrogen atoms correlated well with IA. Molconn-Z electrotopological state indices combined with ClogP and molecular size also correlate to IA. There are a number of other measures of hydrogen-bonding potential, some of which are mentioned below under blood–brain barrier penetration: in general, though, they do not add significantly to the performance of the descriptors above.

More complex modeling methods have also generally identified the same types of descriptors as important for IA. Andrews et al. and Zmuidinavicius et al. use a fragment-based model and a recursive partitioning approach with good results: the Zmuidinavicius algorithm is available commercially from Pharma Algorithms. Jurs et al. have applied a hybrid GA/ANN method with good results. The GA selected 6 descriptors from 162 to be inputs for the ANN: they were the number of single bonds, normalized projection of molecule (''shadow area''), charge on donatable hydrogen atoms, fractional surface area on HBAs, fractional surface area HBA × their charge, and cube root of gravitational index (a density measure). The compound set included actively transported compounds, which is impressive in that such compounds are usually excluded as lying outside the modeled chemical space, but may skew the data set.

5.3.4 Physicochemical Methods

It has long been held that, in the absence of specific transporters, IA is essentially a passive process by which molecules dissolve in the cell membrane from the gut side and dissolve from it into the epithelial cells. The role of lipophilicity is the basis of this hypothesis: IA is limited by how much drug can dissolve in the cell membrane. However, Abraham has shown that IA is not a partition-dominated process (i.e. not one in which the partition of compound into a bulklike lipid phase is important), but a diffusion-dominated one. The role of LogP is therefore misleading – OB is not about dissolving in a bulk phase fast, but diffusing through a barrier.

If IA is essentially a diffusion process, can we not model it as such on the basis of an understanding of the physics of diffusion? Abraham and coworkers have successfully applied this concept using a general solvation equation

$$\log(SP) = c + rR_2 + S\pi_2^H + a\alpha_2^H + b\beta_2^H + vV_x$$

where R_2 is the excess molar refraction, π_2^H is the polarizability/dipolarity, α_2^H is the overall hydrogen-bonding acidity, β_2^H is the overall hydrogen-bonding basicity, and V_x is the McGowan volume. This describes solution of a molecule in physical terms, without consideration of the biological mechanism. In a detailed piece of work based on data for 169 drugs, out of 241 researched (a very substantial data collection exercise in its own right), Zhao et al. showed that appropriate parameterization predicts IA quantitatively with R^2 of between 0.75 and 0.8, providing that OB is not dose limited for large molecular weight drugs (i.e. if the rate of solution is not dominating). The parameters are all calculable in their own right from molecular structure. The ''Abraham descriptors'' have been implemented in a program ABSOLV, which is effective in OB prediction providing the input (and comparative data) is carefully QCed.

Physicochemical methods of this sort are complementary to computational modeling of the lipid membrane – both are based on an understanding of the physics and chemistry of the process that is more "fundamental" than the biology. Both, therefore, are susceptible to improvement either by gathering more biological data to parameterize the models better or from improvements in the model of the underlying processes. By contrast, statistical modeling methods, which today are at least as effective as mechanistic ones, are limited by data and cannot be improved beyond their availability.

5.3.5 CaCo-2 Model

Because IA is complex and expensive to measure, surrogate measures have been developed. The most widely used is the CaCo-2 permeation system, which Artursson described as a model for both passive permeation and P-glycoprotein efflux, although the latter is very variable between experiments and subclones of the cell line. The cell line is derived from a colon cancer, and a monolayer of cells *in vitro* develops tight junctions between the cells that mimic the intestinal epithelium. Permeation assays measure transport of compounds across a monolayer of cells, using a nonpermeant molecule (usually mannitol) as a referent. The MDCK cell line has similar properties, and is also used sometimes.

Despite the cell biological support for the validity of CaCo-2 as a model for IA, and its widespread use in pharmaceutical discovery, CaCo-2 is actually a poor predictor of IA and is not objectively better than most computational models. It works well for comparing the IA of a series of similar molecules, but does not give consistent results between chemical series or between laboratories. Some of these defects can be overcome by more complex methods that control for monolayer quality and boundary layer effects, but the assay is harder and more time-consuming to do, thus removing a lot of the purpose of doing a CaCo-2 screen.

Modeling CaCo-2 itself might therefore seem futile and only useful for drug discovery when an actual CaCo-2 assay is an unavoidable bottleneck in a drug discovery program, or when CaCo-2 is being used as an assay for P-glycoprotein. However, it is also likely that modeling CaCo-2 will give an insight into how to model IA. CaCo-2 data is much easier to obtain than IA data; so as a method of modeling the modeling process, this has substantial value.

CaCo-2 permeation shows the same type of sigmoidal relationship with lipophilicity as IA, with the shape of the curve being modulated by the molecular weight. Several PLS-based models have been constructed, with typical results for small numbers of molecules being $R^2 = 0.85$ to 0.9 using hydrogen-bond count, molecular weight, and lipophilicity terms (usually CLogP). PSA correlates less well with CaCo-2 permeation than with OB in man. More specific improvements to include the strength of hydrogen bonds from nitrogen and oxygen give R^2 of up to 0.935 on small-molecule sets, but do not generalize. The same is observed for IA, suggesting that only very general descriptors are useful for either prediction.

5.3.6 Conclusion for Passive OB and IA

There are active metabolic processes involved in IA and OB, which I consider below. However, for many drugs, it appears that OB can be predicted on the basis of relatively few simple parameters describing size, lipophilicity, and hydrogen-bonding potential. This is plausibly related to the

hypothesis that, for many drugs, IA is the limiting step in OB and is predominantly a diffusion-limited process. Use of sophisticated modeling technology and descriptors has not so far yielded substantially better performance than the simple linear free-energy relationships of Abraham et al. This suggests that either the ideal descriptors for OB and IA have not been identified yet or (more likely) the idea of a unified OB model has been taken as far as it can be. Significant advance will require molecules to be categorized according to whether they passively bind to or are actively transported by specific proteins, interact anomalously with the lipid membrane, or have other molecule-specific behaviors. The first two areas of specific interaction that are likely to be solved are P-gp interaction and CYP metabolism.

5.3.7 P-glycoprotein

P-glycoprotein (P-gp) is an ATP-dependent transporter, and sequence analysis shows P-gp to be a member of the ATP-binding cassette (ABC) transporter superfamily. A major contributor to a drug's IA (and BBB penetration discussed below) is the extent to which it is a substrate for P-glycoprotein. Thus, compounds such as doxorubicin and taxol, which superficially look like good candidates for oral drugs, are poorly orally absorbed because they are excellent substrates for P-gp and so are actively pumped out of the gut epithelium and back into the gut lumen.

Compounds can be substrates or inhibitors of P-gp, and the latter themselves can be (but are not always) transported. So a compound can be affected by P-gp, but can also affect others. This is a substantial issue for predicting drug–drug interactions, where the biochemistry of one drug affects that of another other than by way of their pharmacology.

P-gp is also expressed significantly in the testis, suggesting that it might have a role in preventing reproductive toxicity of some compounds. Members of the human *P-gp* gene family are also known as *multidrug resistance* (MDR) genes, owing to their role in conferring drug resistance on cancer cells: overexpression of P-gp allows the cells to pump out cytotoxic anticancer drugs before they can have an effect and so render the cells resistant to a wide range of drugs that are substrates for P-gp. A similar mechanism involving other members of the ABC transporter family operates in some forms of bacterial antibiotic resistance; so modeling P-gp is of interest outside the domain of ADME prediction.

The mechanism of action of P-gp is unknown. It is hypothesized that P-gp may actually ''hoover up'' drug from the membrane, which would explain why measures of membrane permeability (LogP/PSA combinations) are such effective predictors of BBB and OB even when P-gp, an enzyme, plays such an important role. However, it is not only mechanism as very hydrophilic drugs such as colchicine are also substrates.

P-gp has been modeled *in vitro* and *in silico*. CaCo-2 assays are used as models of P-gp-mediated efflux of drugs in IA and (as mentioned below) other tissue barriers. P-gp is expressed in CaCo-2 cells, although to a variable extent between laboratories, and the extent to which a drug's passage through a CaCo-2 monolayer is affected by P-gp can be judged by measuring its rate of diffusion across the cells in the presence and the absence of a known inhibitor of P-gp, such as verapamil. Such P-gp measurements can themselves be used as guides to drug design (on a general rule that being a P-gp substrate will reduce OB and so is undesirable) or be used as components of other models of OB.

Substantial work has gone into defining what the substrate and inhibitor selectivity of P-gp is. The enzyme tends to be active on large molecules and has a ''preference'' for hydrophobic, amphipathic molecules carrying a positive charge at physiological pH and containing a planar ring system. Apart from these general constraints, conventional SAR have found it to be very unspecific, and even these ''rules'' are frequently violated. Many P-gp substrates are uncharged at physiological pH (e.g. colchicine), and several uncharged cyclic and linear hydrophobic peptides and ionophores have recently been described as P-gp substrates.

MultiCASE has been used to identify fragments (''biophores'') that may be important for P-gp substrate status, but it is considered unlikely that these are exhaustive or general. Seelig finds that the enzyme has a general requirement for molecules that have 2 or 3 electron donor groups or hydrogen-bond acceptor groups separated by 2.5 Å or 4.6 Å, but many exceptions exist. Ekins et al. have used the Catalyst QSAR modeling software to generate several different models of P-gp on the basis of different modeling approaches and training sets. All the models have a number of hydrophobic features and most have an H-bond feature; however, what these features are and how they are arranged varies with the molecules used to train the models. Some work using a fragment-based GP approach has produced models of P-gp specificity, but these again are fairly local to the chemical space on which they are trained.

Overall, therefore, it is not possible to do more that estimate the chance that a molecule will be a substrate or an inhibitor of P-gp, and it is not practical to estimate the extent to which it will be a substrate or inhibitor at a given concentration. The input of P-gp into IA, OB, or BBB models is therefore usually as a measured input parameter. Whether further structural information on P-gp will improve this is not clear.

5.3.8 Other Transporters

Specific transporter proteins are responsible for efficient uptake of hydrophilic biological molecules that would otherwise not be absorbed from food. These can also transport drugs that have some features in common with their natural substrates. There is some very early limited QSAR results predicting compounds that are transported by specific proteins, which has also been used to attempt to design this property into new drugs. Specific transporters that have been examined include monocarboxylic acid transporters (which are also relevant for BBB penetration), glucose transporters, and peptide transporters. There are also specific transporters in the kidneys that influence clearance rates: some ionic drugs are actively transported into urine by transporters that excrete natural compounds, especially uric acid, choline, histamine, and are transported into bile by transporters that excrete charged bile acids and steroids.

However, in general, modeling of these systems is less advanced than modeling P-gp, and it does not play a significant role in predicting ADME properties yet. This is a very active area of research, and the importance of transporters in absorption, distribution, and excretion means that substantial effort and hence, it is hoped, substantial progress will be made in the next few years.

5.3.9 Metabolism and Intrinsic Clearance

Oral bioavailability is the combined effect of how much drug is absorbed from the

intestine (a combination of passive absorption and transporter effects) and how much is subsequently removed both from the intestinal cells and from the hepatic portal blood supply by liver metabolism before it reaches the systemic circulation. Thus, whether a drug is metabolized, and at what rate it is metabolized, is a critical OB-related ADME issue. Thus, for example, grapefruit juice can enhance the OB of some compounds because it contains powerful inhibitors of CYP3A4, a drug-metabolizing enzyme present in gut and liver that would otherwise degrade the absorbed compound. Related to this is predicting what the metabolite of the drug is and hence whether it is likely to be active or toxic.

Metabolic rate is related to ''intrinsic clearance'' – the inherent rate at which drugs are cleared from the blood by metabolism, mainly in the liver. Intrinsic clearance is usually estimated *in vitro*, using liver tissue slices, cultured primary liver cells, hepatocyte cell lines, or microsomes. The last of these are membrane fractions from liver tissue and are a widely used reagent: they contain a full complement of P450 enzymes from the species in question and can be quality controlled by reference to known metabolites.

None of these methods are ideal: primary tissue is difficult to obtain and store, microsomes have to be prepared from tissue (although they can be stored frozen), primary hepatocytes vary in their level of differentiation, and hepatocyte cell lines do not usually reflect more than a fraction of the metabolic diversity of the liver. However, these tests are much faster and cheaper than animal metabolism experiments, not least because they can be done on milligrams rather than grams of test material, so they have become standard practice.

The principle clearance is by a family of P450 heme-containing monooxygenases termed *CYPs*. The most important is CYP3A4, which metabolizes over half of all drugs to some extent and is also present in the intestinal mucosa.

In principle, as CYPs are a well-characterized family of enzymes with known modes of action, all the technology of conventional drug design should be able to be brought to bear on them. Lack of crystal structures for the human enzymes has hindered this (the structure of human CYP3A4 was solved in 2002, but is still commercially confidential). However, homology modeling with CYPs from other species has lead to a major modeling effort by Segall et al. using quantum chemical calculations to probe the interaction of the heme with the substrate and molecular mechanical and docking approaches to find which substrates will fit the enzyme. This has shed light on the mechanisms of CYP3A4 interactions with its substrates and in some cases can predict where on the substrates the enzyme will attack (and hence what the product will be). However, for many others, details of the steric interactions between the enzyme and substrate foil modeling attempts, so that (for example) prediction of terfenadine metabolites is completely incorrect. Thus, while these approaches are of value, they still have to be used in conjunction with structure-matching and other heuristic approaches.

Until improved structural chemistry information allows accurate computational chemical calculations of interactions of substrates with CYPs, we must fall back on QSAR approaches. Inspection of the substrates of CYP3A4 and P-gp show that there is substantial overlap, and this has lead to speculation that they are structurally related. It is more likely that this similarity

is because they have evolved specificity to dispose of similar types of molecules (i.e. broadly hydrophobic molecules of the size of plant and bacterial secondary metabolites) and not because of any genuine similarities. Incorporating both separately into pharmacokinetic models is more successful than trying to develop a unified model for these two enzymes.

CoMFA QSAR of hepatocyte and microsome metabolism produces an $R^2 = 0.59$ for quantitative prediction of the rate of metabolism, a challenging modeling target. The CoMFA 3D pharmacophore, depending on training set, combines hydrophobic domain(s), a hydrogen bond acceptor, a ring aromatic feature, and a positively ionizable feature. Use of the Cerius2 GA also produces a descriptor-based model, with particular emphasis on the chlorine atoms in molecules as well as on descriptors consistent with those above. These are features of which one or more have to be present for rapid hepatic clearance. CYP inhibition (formally, pK_i) has been predicted with some success with a combined GA/ANN approach and using GP alone with a fragment-based descriptor set (White et al., Amedis Pharmaceuticals, unpublished). Objectively, these models are as good as rapid *in vitro* screens for CYP metabolism or inhibition at predicting human clearance; however, they are not likely to be widely accepted until they are substantially better.

The other approach to CYP prediction is one widely implemented in toxicology but only minimally in ADME. This is the use of databases of prior examples coupled with some suitable similarity score to find the nearest examples to a test compound. These can be a simple database and search engine or a more sophisticated expert system. These do not have any greater success than the mathematical modeling methods mentioned above and are inherently limited by the need to have humans (with their limited bandwidth and inherent biases) select as well as input the data. However, their substantial advantage for the user is that they can provide explanations for their answers, tracking back ''hits'' to original literature papers: this provides the user with an understanding of the scientific context of the result as well as a number. It is questionable how real the value of this is, as few will read the original papers in depth to uncover any methodological flaws, unseen biases, or other problems that would render the comparison with their present problem irrelevant. However, subjectively, users feel better about using the system and so it is used. This is a lesson other ADME modelers have been slow to take on board. Systems of this sort include MetabolExpert and Meteor.

5.3.10 Conclusion of P-gp, Transporters, and CYPs

In conclusion, while, in principle, predicting how drugs will interact with single protein targets such as CYP and P-gp is more solvable by a mechanistic, computational chemical approach, this is not yet practical, and the data-driven, mathematical modeling approaches used for higher-level ADME properties are still at least as useful. This is partly because transporters are integral membrane proteins, and hence determining their 3D structure is hard. However, equally problematic is the fact that their binding sites are highly nonspecific, being, in effect, hydrophobic ''buckets'' with a catalytic site in them, and docking molecules into such ill-defined structures is extremely prone to error. Structural information will improve, but the docking problem is likely to remain.

6 Distribution

Once a drug has successfully negotiated the gastrointestinal tract and the liver, it enters the systemic circulation and from there can go to all the organs of the body. Predicting how this occurs is important to predicting the concentration of the drug at any time in its target tissue or receptor. This breaks down broadly into a system-wide measure of where the drug goes (volume of distribution, V_d) and consideration of how it penetrates specific organs or tissues.

6.1 Volume of Distribution and Protein Binding

Formally, V_d is the dose of the drug divided by its concentration in plasma, that is, the apparent volume of plasma in which the drug is dissolved. It represents a combination of the literal volume of the body that the drug dissolves in and the extent to which it binds to body components. Paradoxically, V_d can be larger than the volume of the patient who received the drug: if the drug binds tightly to (for example) bone or fat, these tissues will extract the drug from plasma, leading to an unexpectedly low concentration and hence a high V_d.

A range of approaches to V_d prediction, including advanced modeling techniques such as ANN and GP, have been quite unsuccessful. This is probably because, although V_d is simple to measure, it is the result of an enormously complex phenomenon of traffic of compound into and out of all the compartments of the body, both through diffusion and partition processes and through active transport. Only complex integrative PK models (see below) that explicitly model many compartments and tissues in the body and include measured values for drug transport and partition come close to modeling V_d successfully.

A major component of such models is plasma protein binding (PPB). Pharmacologists wish to determine PPB in its own right, especially for drugs that bind to plasma proteins very tightly and so are essentially not present in plasma as free drug at all. The extent of PPB may also influence intestinal absorption, an effect modeled in CaCo-2 cell systems. So this is a useful parameter to know and hence to model.

Serum albumin (HSA) is the dominant protein by mass in plasma, being present at 0.6 mM concentration, which is usually far higher than the concentration of any drug. Binding is therefore unusual in that it does not saturate, and very low pK_a can result in significant drug binding. Neutral drugs bind to HSA through a predominantly nonspecific hydrophobic interaction, and this is reflected in modeling results: Colmenartejo et al. use a GA to select among a large number of candidate descriptors and find that the predictions ($R^2 = 0.82$, $Q^2 = 0.73$ for predicted affinity of binding to HSA) are dominated by LogP. Binding has been modeled with quantum mechanics–calculated descriptors – H-bond donors, HOMO energy, PSA, dipole moment, ClogP, and a connectivity measure indicating six-membered rings. Models select these parameters in a way that is related to general shape and overall hydrophobicity. Outliers tend to be acidic compounds that bind to different binding sites in HSA.

Basic drugs bind primarily to α 1-acid glycoprotein; there has been little modeling of binding to this protein.

PPB would be expected to influence V_d substantially, as a major ''sink'' for drug molecules. This obvious relationship can

be used to derive a formula for V_d on the basis of PPB, protein concentrations in plasma, and similar volumes and concentrations for other compartments, such as specific tissues and the fluid between cells. Lave et al., Lombardo et al., and Poulin and Theil discuss general equations of this sort, relating PPB to V_d, and they are modestly successful: Poulin and Theil obtain $R^2 = 0.61$ for all drugs. However, despite the logic of the approach, in man at least V_d and PPB are almost completely uncorrelated ($R^2 = 0.04$ – see Fig. 6). The equations may therefore work only because PPB is a surrogate for lipophilicity, as many models include an explicit LogP term, and LogP is independently useful as an indicator of V_d.

As PPB and V_d are apparently largely unrelated for most drugs (despite theory), some authors have gone on to examine those limited PPB modes that do substantially affect PK. For the pharmacologist, the critical aspect of PPB prediction is not differentiating 25% from 75% (which can be compensated by dosing) but predicting what drugs will be very tight binders (over 90% bound and especially over 99%), which seriously distort the PK. Kratochwil et al. built a model specifically to address this, to distinguish 90% from 99.9% binding: PPB is significantly more correlated with V_d in these high-binding domains. This application illustrates the need to build models to answer development questions rather than purely scientific ones.

6.2 Blood–brain Barrier

Distribution to well-perfused organs is usually rapid, and the concentration is

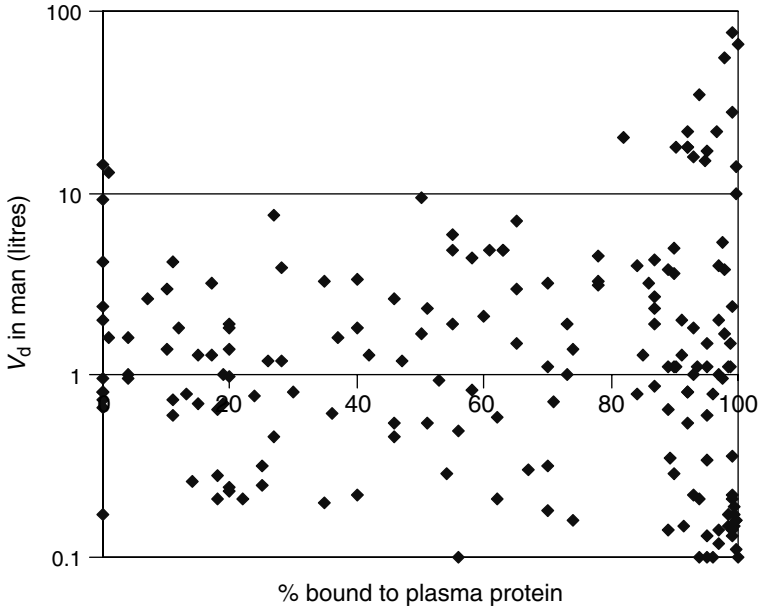

Fig. 6 Plot of fraction of drug bound to plasma protein (*x*-axis) versus volume of distribution (*y*-axis) for 184 compounds for which both parameters are reported in Goodman and Gilman or in Dollery.

simply dependent on blood concentration. However, distribution to some organs and tissues is slower, notably to adipose tissue (fat, where concentrations depend on build up of a reservoir in the fat itself, and hence are strongly modified by lipophilicity) and brain.

Penetration of drugs to the brain is a major development issue. The brain is one of the most biochemically complex organs of the body, but the complement of receptors shares many similarities with receptors outside the central nervous system (CNS). Thus, for example, histamine receptors are almost identical in the brain and the periphery; so the only difference between antihistaminic drugs that sedate (first-generation drugs such as diphenhydramine) and second-generation ones that do not (such as loratidine and terfenadine) is that the former penetrate into the brain and the latter do not. So determining how much of a compound enters the brain is important both for compounds that are meant to have a CNS effect and for those that are not.

Brain penetration is a modeling target because there is a barrier to passive diffusion of compounds out of the blood and into the brain tissue (called the *blood–brain barrier – BBB*), made primarily of the endothelial cells lining the brain capillaries. These are connected by tight junctions and express P-gp that actively pumps lipophilic molecules out of the endothelial cells. Entry into other tissues is not usually the target of *ab initio* modeling in the same way, because they are not protected from the blood by the same type of discrete barrier.

Most drugs enter the brain by passive diffusion – a few are targeted at specific transport mechanisms such as the ferritin transporter, in the expectation of active transport. So properties that enhance diffusion through the biological membrane will enhance BBB penetration (pBBB, almost always expressed as a log scale measure). Consequently, as would be expected, measures of lipophilicity and hydrogen-bonding potential feature substantially in predictions of pBBB. Modeling seeks to model the ratio of a drug to that in whole brain (the usual animal endpoint) or blood to cerebrospinal fluid (CSF), the measurement in man in most cases. Either measurement is practical but slow and expensive. It is also possible to estimate whether a compound enters the brain by examining whether it has any CNS pharmacology, providing that there are receptors in the CNS to which it could bind if it could get there (as with the antihistamine example above).

All attempts to model pBBB are faced with a very limited data set. Partition between blood and brain can only be done in whole animals and requires a substantial number of animals to be sacrificed and analyzed per data point; this is therefore very expensive data. The largest described, compiled by Amedis Pharmaceuticals from literature sources, contains only 167 molecules for which quantitative partition between brain and blood has been measured. Most studies use substantially fewer molecules, and some recycle data sets that have transcription errors or out-of-date and inaccurate values.

In general, pBBB is strongly correlated with linear functions of LogP, LogPcyh (LogP in water/partition coefficient between water and cyclohexane), PSA, and hydrogen-bonding potential. An algorithm based on PSA and molar volume gives $R^2 = 0.71$. LogPcyh is often found to be better than LogPoct when used with other parameters. A good model of pBBB can be derived using LogP, PSA, and H-bond

acceptor count, or other lipoaffinity measures (100 molecules give an $R^2 = 0.73$). Unlike the general finding for OB, several authors have found significantly better correlation of pBBB with a full dynamic PSA calculation than with quick approximations; however, a fast PSA combined with ClogP can provide $R^2 = 0.77$.

PSA alone can be used to predict pBBB: Kelder et al. found that

$$\log(\text{pBBB}) = 1.33 - 0.322\ \text{PSA}.$$

This is unrealistic for all molecules, as it suggests that all molecules with zero PSA have the same pBBB – methane has a pBBB similar to polythene or graphite – but works well within the domain of most druglike molecules, again emphasizing the need to design algorithms to solve practical problems.

Crivori et al. studied the BBB relevance of 72 Volsurf descriptors and found excellent PCA breakdown of compounds into BBB penetrant and partially nonpenetrant compounds without training, which suggests that some of the major chemical features of these molecules (rather than subtle ones) determine their BBB penetration.

With success in physicochemically based models for OB, which assume that the penetration of the gut-epithelial barrier is a diffusion or partition process, the same approach has been used to generate models for pBBB. A model based on the free energy of solvation in water (a calculated thermodynamic measure) achieves an $R^2 = 0.72$. Lombardo et al. used the free energy of solution in water to derive a prediction of pBBB to $R^2 = 0.67$. They considered whether other parameters could improve this and concluded that they could not, which they said was not surprising because the Delta G calculation includes calculation of energy needed to create a cavity in the solvent (reflected in PSA) plus interaction between the molecule and the solvent (reflected in LogP).

On the basis of the understanding that pBBB is primarily a diffusion property, Abraham's group (Platts et al.) derived a version of his general solvation equation to predict pBBB to $R^2 = 0.9$ in a series of very powerful papers. They observe that this model does not predict compounds with carboxylic acid groups well and suggest that these are transported at least in part by the known carboxylic acid transporter.

Two other types of descriptors have been identified as important by other studies. Norinder and Haeberlein have developed the equivalent of the Rule of Five for pBBB: $N + O < 5$, $\text{LogP} > (N + O)$ (N, O = number of nitrogen and oxygen atoms respectively). Applying this gives a C_a of between 0.85 and 0.9. Luco and White et al. (unpublished) have used a range of topological connectivity and atom-type descriptors to build models that had $Q^2 = 0.75$ and $C_a = 0.92$ (for a classification model), respectively. The Luco model again finds the number of nitrogen atoms to be significant, as well as combined measures of hydrogen-bond donor and acceptor counts, differential connectivity, a measure of the information-theoretic complexity of connectivity of the molecule, and the number of different elements in the molecule. The White model is a multidescriptor model built using GP and using dozens of descriptors, but again selected molecular connectivity descriptors and nitrogen atom content as well as PSA as key elements of the model.

Unlike OB, therefore, pBBB modeling results suggest that current approaches and data sets are capable of finding new models to predict brain entry beyond those based on simple diffusion-based or thermodynamic systems and specifically that there is a difference between N

atoms and other polar atoms, and that molecular size, shape, and "floppyness" are important to pBBB prediction.

6.3 Conclusion on Distribution

Unlike OB, it seems likely that there is room for improvement in the descriptor sets and the models used for pBBB prediction. There is also substantial room for improvement in the prediction of other distribution parameters such as V_d, to which advanced modeling methods have been applied only sporadically. Distribution modeling is therefore an area in which substantial advances are likely to be made over the next few years.

7 Integration of Predictive Models

I have stated that true Type-I models of human PK parameters are not feasible, and we have seen that, depending on the endpoint, a variety of Type-V models have been built.

Type-II and Type-III models, in which either modeled or measured subprocesses are integrated mechanistically to provide a model of drug physiology, are widely applied. By contrast, Type-IV models, in which measured inputs are integrated statistically to provide a picture of the whole physiology of the drug, are rare. This is because the top-level interactions and mechanisms of physiology are well understood, and if the parameters of the components of these models can be modeled or measured, there is no need to guess at how macroscopic physiology works.

Integrating low-level measures into high-level systems is well known for OB, where many of the subsystems are well known (even if the specific effects of a particular drug in those systems need to be modeled or measured). For example, Agoram et al. use PLS and ANN models based on fragments and 3D structure–based descriptors to predict MDCK cell permeation, LogP, solubility, and molecular diffusivity. These are then integrated with measured PK parameters to provide the constants in the differential equations for an advanced compartmental absorption and transit (ACAT) model of OB, to determine the rate, extent, and approximate gastrointestinal location of drug liberation (for controlled release), dissolution, passive and carrier-mediated absorption, and saturable metabolism and efflux. The model has 18 GI compartments – stomach, seven small intestine compartments, colon, and nine enterocytes, plus liver, systemic circulation, kidneys, and other compartments, with coupled differential equations for concentration in each compartment. The software operates by numerical integration of the large set of differential equations and provides good results for many drugs (for example, it correctly predicts the dose-dependent bioavailability of propanalol, the effect of grapefruit juice on overall bioavailability of CYP3A4-metabolized drugs, and other "problem" PK outcomes). It is available commercially as GastroPlus.

Leahy et al. at Cyptotex have built integrated models specifically to exploit the data generated by *in vitro* screening assays such as CaCo-2 and the CYP assay. The models include 114 parameters and 14 tissues (lung, muscle, adipose, skin, kidney, brain, gut (9 segments), stomach, spleen, pancreas, liver, heart, kidney, reproductive), with parameters for blood flow, fluid volume, and other physiological

properties gained from the literature. The models can be tailored to different species using the physical parameters of those species and predict half-life and AUC well even for problematical drugs.

Both these examples, and others, require experimental data to tie the models to the real world. Can a purely *in silico* mechanistic model be developed (i.e. a true Type-II model)? At the moment, the answer is definitely "no" for nearly all physiological processes. The nearest approach is in cardiac electrophysiology, where the coupled differential equation models effectively demonstrate the highly nonlinear behavior of the heart to some drugs on the basis of relatively sparse experimental data and substantial literature understanding of the heart. The work of Noble et al. has been developed to the point where it can be used as an adjunct to late-phase clinical trials. Even here, though, models of the underlying low-level processes are not sufficiently accurate to act as inputs to the higher-level model. As an example, HERG IC_{50} can be predicted in a statistical QSAR model to within a log unit (Bains et al.). However, its value needs to be predicted to within a factor of 2 to predict whether HERG blockade will affect the cardiac rhythm. Here, as elsewhere, modeling is limited in part by the technology available but principally by the quality of the data available.

8 Overall Conclusion and a Caution

The statistical modeling tools discussed here have provided some valuable estimators of ADME parameters and will continue to do so. With the possible exception of pBBB, at the moment, all models are almost entirely data-limited. There have been no new "ADME-specific descriptors" since the introduction of the use of PSA and no obvious ones that can be used. Research in this area will therefore work on new theoretically driven approaches (which will come up with completely new ways of describing molecules or biological systems, but will have to wait for the new theories before they can even be conceived), brute-force approaches such as the GP or ANN methods (which can discover new combinations of descriptors on their own, but take enormous amounts of computer power to do so), or better data sets. Ideally, a combination of the second and third options will inform the first, leading to ADME predictions that are sufficiently soundly based in scientific understanding as well as theoretical rigor to be used widely as the basis of decisions.

In the meanwhile, practitioners are reminded to be cautious about the use of the very powerful statistical techniques discussed here. They can find correlations between almost anything. It is essential that such statistical links are tested thoroughly and explored theoretically before any reliance is placed on them.

Acknowledgments

My thanks to Antranig Basman (Amedis) and David Livingstone (ChemQuest) for their comments, and to Robert Scoffin (CambridgeSoft) for many useful discussions and much coding.

Functional Genomics
A field of global functional analysis of genome based on complete sequence data.

Since Wollman & Bronfenbrenner introduced this organism in the 1930s, *Escherichia coli* has become one of the most thoroughly studied organisms in biology. The discovery of conjugation by Lederberg and Tatum in the 1940s using sets of defined mutants triggered a revolution in biology through clarification of the concept of ''gene.'' It is a clear testament to the importance of this organism in modern biology that nobody can escape from using *E. coli* to study genes or genomes. For over 50 years, extensive and sustained efforts of many microbiologists, geneticists, biochemists and bioinformatists around the world contributed to the detailed analysis of the functions of many genes and gene products in these bacteria.

1 The *E. coli* Genome Sequence

The *E. coli* genome sequence was determined through independent efforts of both the United States and Japanese groups by using two different strains of *E. coli* – MG1655 and W3110 respectively. These strains diverged from the same ancestral strain about 50 years ago causing slight differences between them, including the large inversion involving the ribosomal RNA genes (see below). The complete genome sequence analysis revealed precise differences between the two strains. Comparison of the genomes of strains MG1655 and W3110 revealed relatively infrequent base substitution mutations, in the order of 10^{-5} per bases in the protein-coding region. On the other hand, dynamic genome rearrangements such as insertions and deletions are not uncommon. In summary, the *E. coli* genome can tolerate large rearrangements, such as insertion, deletion and recombination rather than microscale changes like base substitution. In 2001, pathogenic *E. coli* O157, which is very closely related to *E. coli* K-12, was subjected to genomic sequencing by two groups (in the US and Japan). The results obtained with this pathogenic strain agreed well with the above findings with strain K-12. The *E.coli* O157 acquired its pathogenicity mainly by horizontal gene transfer mediated by a temperate bacteriophage.

2 ORF Predicted from the Complete Genome Sequence of *E. coli*

Extensive studies of a few model organisms including *E. coli* and *Saccharomyces cerevisiae* elucidated the functions of many genes and gene products particularly by using techniques of genetics, biochemistry and physiology, and so on. Complete genome sequence of *E. coli* revealed the presence of about 4400 predicted ORFs. More than 2000 genes have so far been characterized and classified by their function, whereas the rest remain functionally uncharacterized (Fig. 1). Network analysis

Functional category	Number of ORFs	%
Unknown	2001	45.5
Transport/Binding proteins	377	8.6
Energy metabolism	363	8.3
Other categories	300	6.8
Cell envelope	204	4.6
Translation	163	3.7
Central intermediary metabolism	156	3.6
Amino acid biosynthesis	138	3.1
Biosynthesis of cofactors, prosthetic group, carriers	129	2.9
Cellular processes	127	2.9
Regulatory functions	124	2.8
Purines, pyrimidines, nucleosides, and nucleotides	107	2.4
Replication	92	2.1
Fatty acid/Phospholipid metabolism	60	1.4
Transcription	52	1.2

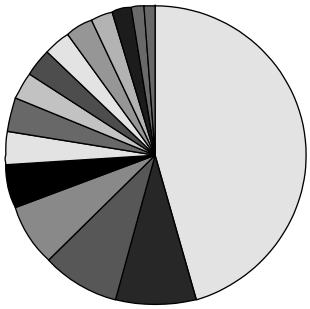

Fig. 1 Functional classification of *E. coli* ORFs.

of mutual functional relationships between genes or gene products has just started.

Accumulation of numerous genomic sequence data accelerated comparative approach, providing the basis for distinction between two ways of genes to be homologous: orthologous genes are homologues between species, and paralogues are those that descend directly from copies of a gene that duplicated within an ancestral genome. Orthologues are therefore good instruments for building phylogenetic trees of organisms, and paralogues are useful for understanding the course of protein evolution. Comparative analysis using the full set of genes in *E. coli* revealed two classes of genes: paralogues and nonparalogues. Sets of paralogous genes could be considered to have descended from ancestral genes by duplication and divergence. The concepts of ''protein family'' and ''module'' were discussed by Riley and her colleagues: ''module'' defined as a long conserved segment, usually larger than 100 amino acid residues, within a protein and an element of sequence that has independent evolutionary history. It may also correspond to a functional unit and contain several domains that are defined as structural units. These functional units are capable of independent existence but in some cases, joined to another module of independent function in a multimodule protein. For example, proteins involved in transport or binding proteins form a large protein family in *E. coli*, and some of them (enzyme, transport protein and transcriptional regulator protein) share modules for binding certain ligands.

3 Repetitive Sequences, Sites, RNA Genes, etc.

Many kinds of repetitive sequences are found within the genome and some of them have important physiological function. Distribution of repeats on the chromosome is not random and seems to be

related to some feature of DNA replication. Repetitive sequences in *E. coli* are encountered in many contexts. Various classes repeats are present in diverse prokaryotes, including *E. coli*. Coding sequences such as ribosomal RNA genes, transfer RNA genes, and insertion sequences are present usually in multiple copies but their copy numbers are relatively low. Other interspersed repetitive DNA sequences are relatively short but abundant and located within intercistronic noncoding sequences. The latter families of repetitive sequences are listed in Table 1.

E. coli has 7 copies of rRNA coding genes (*rrn*) and an additional copy of 5S rRNA coding gene. Other rRNA related DNA sequences named TRIP, showing significant similarity to 5S rRNA, were recently found, which may have important roles related to 5S rRNAs. The rRNA genes are located within half of the chromosome that contains the origin of DNA replication (*oriC*), whereas many of the TRIP sequences are located in the other half of the chromosome. Moreover, *rrn* and some of the related TRIP sequences are distributed symmetrically on the leading strands on both sides of *oriC*. Consistent with this location, transcription of *rrn* operons generally proceeds away from the replication origin (Fig. 2).

Repetitive sequences such as rRNA genes provide a driving force for genome rearrangement. A large inversion of the genome between rRNA genes has been documented in *E. coli*, and one such inversion was found in the strain W3110. Although the direction of *rrn* gene transcription is strictly restricted away from the replication origin, the inversion in *E. coli* appears to be stable because the geometric relationship between *rrn* operons and the replication origin are preserved.

Insertion Sequences (IS) represent another family of repetitive elements and cause genetic variation among different strains of *E. coli*: both the abundance and distribution of insertion sequences can vary in different strains. Strain W3110, whose sequence was determined by the Japanese group, contains about 60 ISs

Tab. 1 Extragenic highly repetitive sequence families.

Sequence	*Size [bp]*	*Copy number*
BIME	40 ~ 400	~800
Ter	30	63
BoxC	56	36
Iap	29	23
IRU	127	19
RSA	152	6

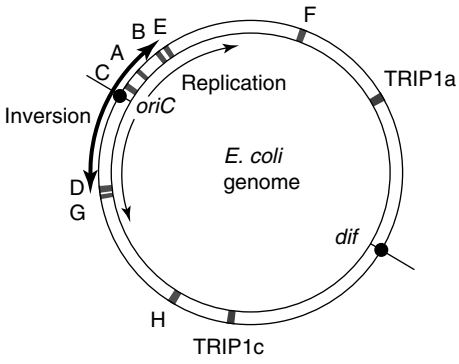

Fig. 2 Ribosomal RNA genes (*rrnA*-H) and related sequences. The arrow represents the inversion loci of W3110 between D (*rrnD*) and E (*rrnE*).

that belong to at least 10 distinct families and at least 10 ISs differ in their location when compared to another strain MG1655, whose sequence was determined by the US group. These results testify to a great variability in both number and family of ISs in closely related strains. Although it is not possible to decide whether these elements were primarily selected on the basis of their beneficial character, or whether they act as genomic parasites, there are a number of examples in which direct selection for certain mutants resulted from transcriptional activation mediated by IS.

Interspersed repetitive sequences represent relatively short (usually less than 500 bp), noncoding, intercistronic and dispersed elements found in bacterial genomes. Six classes of highly repetitive sequences, BIME, IRU, Box C, RSA, iap, and Ter Sequences have been identified (Table 1). Although they are highly repeated, they do not constitute more than 2% of the total *E. coli* DNA and this explains the failure of identification by the classical experimental methods. These sequences were mostly discovered by computer analysis of sequence data.

None of these sequences encode proteins, and are dispersed throughout the chromosome. BIME is the best documented case, originally identified as REP (*R*epetitive *E*xtragenic *P*alindromic), which consists of a 38 b consensus palindromic sequence and can form a stable stem-loop structure with a 5 bp variable loop in the middle. Clusters of REP element with several sequences form a complex mosaic structure called BIME (*B*acterial *I*nterspersed *M*osaic *E*lements). Approximately 800 BIMEs appear to be homogeneously distributed over the entire chromosome. BIMEs are found in extragenic locations at the 3′ ends of operon or between two genes of an operon, but rarely upstream of the first gene of an operon. Specific interactions of DNA gyrase, IHF and DNA polymerase I with BIMEs were reported, although the functional importance is unclear. The BIME-Pol I interaction suggests possible amplification of BIME regions.

4 Post Sequence Genome Project

Upon completion of genome sequencing, efforts were made to construct various resources including a complete set of ORF clones and of deletion mutants. These resources should provide basic tools for systematic functional analysis of the genomes that would eventually develop into systems biology.

Furthermore, genome-wide analysis of transcriptional regulation (transcriptome), protein dynamics (proteome), flow of metabolites (metabolome) have rapidly developed to make the best use of DNA sequence information (''-ome'' is a Greek suffix for ''whole'').

Although *E. coli* is among the most thoroughly studied genetic systems, half of the genes had not been characterized experimentally. One can now identify all of their genetic components, such as protein-coding genes, RNA genes, and regulatory elements. It is, in other words, limited number of genes to be analyzed, although almost half of them remain to be functionally analyzed. Moreover, global analysis of regulatory network of transcription, protein–protein interaction and so on, has just started.

DNA sequence analysis identified about 4400 protein-coding genes in *E. coli*. The power of genetically tractable model organisms is that they can facilitate the analysis of physiological gene function

in vivo. Precise genetic manipulation is particularly important for functional genomics. Genome sequence data permitted to design oligo DNA primers for precise amplification of ORFs and a complete set of histidine tagged ORF clones, fused with and without GFP gene, has been obtained and is available upon request for *E. coli* (reviewed by Mori et al.).

One approach for systematic functional analysis is gene deletion (replacement) by homologous recombination. Targeted gene replacement, once thought to be difficult in *E. coli*, can now be dealt with by using techniques developed by Wanner and colleagues. These systematic approaches to construct resources for functional genomics would rapidly raise *E. coli* to one of the leading organisms in the field of functional genomics.

4.1 Transcriptome Analysis

With the advance of genome research, many novel techniques have been developed including DNA microarray or DNA chip technology that are extremely useful for analysis of global gene expression. Generally, DNA microarray is defined as an orderly arrangement of tens to hundreds of thousands of unique DNA molecules of known sequence usually on a glass slide. Each unique DNA molecule is individually synthesized on a rigid silicon plate (generally called *DNA chip* and developed by Affymetrix Co.) or presynthesized DNA molecules (synthetic oligonucleotides or polymerase chain reaction (PCR) products) are spotted and immobilized on the slide glass. The use of DNA microarray to study *E. coli* gene regulation was first illustrated by Blattner and colleagues, and has rapidly expanded to analyze various aspects of transcriptional regulation.

4.2 Proteome and Interactome Analysis

Technology for global analysis of cellular proteins has been established since 1975 as two-dimensional polyacrylamide gel electrophoresis developed by O'Farrell. And *E. coli* has a long history for protein cataloging in 2D gel. However, new technology called *matrix-assisted laser desorption ionization-mass spectrometry* (MALDI-MS) accelerated protein identification dramatically. Currently, the most widely used method for proteome analysis is 2DE, followed by identification by mass spectrometry in high-throughput. Proteomics has now developed on global scales not only for identification and cataloging of all the proteins expressed in a cell but for global analysis of protein–protein interaction, called interactome, using the yeast two-hybrid system or related methods. As an alternative method for global interaction analysis, His-tagged-pulldown technique widely used as a fusion tag in expression of recombinant proteins has been used to allow affinity purification. A complete set of His-tagged ORF clones has already been established, and the comprehensive protein–protein interaction analysis is now under way. Mass spectrometry is also used for identification of copurified interacting candidate proteins.

5 *E. coli* Genome as a Model for Systems Biology

Biology itself is now standing at the turning point from the past descriptive biology to the modern quantitative systems biology. Many systematic approaches such as DNA microarray or proteome analysis have been adopted that should help to

understand the cells comprehensively as a system. Among model organisms, *E. coli* is especially important in this field because of enormous accumulation of biological knowledge and experimental methodologies. Scientists can now describe in exquisite detail many of the molecular parts and processes in a cell. Complete genetic information is now available for many organisms in all life kingdoms. Yet, we still do not have a comprehensive computational model of a living cell.

The International *E. coli* Alliance (IECA) was formed to tackle this fundamental biological problem in November 2002. IECA's mission is to consolidate global efforts to understand a living bacterial cell. Scientists around the world are working together to create a complex computer model, integrating all of the dynamic molecular interactions required for the life of a simple, self-replicating cell. An *E. coli* cell model will have immediate practical benefits and will significantly advance the field of computational systems biology. Generation of a computerized *E. coli* cell will add powerful new tools to our existing arsenal of discovery, including virtual experimentation and mathematical simulation. Ultimately, these biological and computational tools could be useful in both drug discovery and in the design of bioenhanced nanomachines. Furthermore, development of a virtual system for experimentation on the *E. coli* cell will be extremely useful for understanding more complex cells and contribute to the development and validation of *in silico* models of human cells. Biology is now changing to become a big science and *E. coli* might become one of the leading organisms in this new biology as was the case in the field of molecular genetics.

6 Useful *E. coli* Websites

As Internet technology advanced, the importance of websites rapidly increased.

Tab. 2 Useful websites of *Escherichia coli*.

Keywords

E-Cell
Short form for Electronic Cell. A tool for modeling and simulating cellular pathways.

Self-supporting Cell
A virtual cell with 127 genes sufficient for survival.

In Silico Modeling
Describes a model building process using computers.

Mycoplasma Genitalium
A microorganism with the smallest number of genes.

Virtual Erythrocyte
An *in silico* model of whole erythrocytic metabolism.

Modeling
A practice of abstracting and interconnecting elements leading to a hypothesis. Models can be qualitative or quantitative or an optimum mix of the two.

Simulation
A process of visualizing a model dynamically.

Cells perform complex tasks with sheer simplicity. They are remarkable, tiny factories where thousands of jobs are performed in parallel and with statistical precision. The grand challenge for the scientific community is to understand the entire structural and functional design of the cell and fine-tune it for scientific applications ranging from basic to pharmaceutical. In a traditional experimental set-up, it is difficult to focus on more than one problem though recent high-throughput techniques have enabled investigation at the ''whole'' organism level. Nevertheless, data coming from these experiments are often noisy and require a large number of replicates to validate a single observation. Furthermore, the statistical treatment of the high-throughput data is also controversial. To overcome the physical and conceptual limitations, we need innovative sets of tools and strategies to address a problem. Recently, a spurt

of articles published in *Nature* (Nov 14, 2002 issue) lends credibility to the idea of using *in silico* approaches for understanding and engineering whole cellular systems. E-Cell is one such tool that has been specifically designed to model and simulate cellular pathways. It has been successfully used to create a self-sustaining cell with 127 genes, that is, just stable enough for survival. In this chapter, some of the basic modeling concepts, their importance, the role of E-Cell, and the future challenges that await the modeling community will be discussed.

1 Introduction

A model is an optimal mix of hypotheses, evidences, and abstractions. Models are the closest replicas of phenomena with sound diagnostic and predictive abilities. They are easily understood, controllable, and analyzable even for large and complex data. The aim of whole-cell modeling is to provide both a conceptual basis and a working methodology for the entire cell by adopting a formal modeling process in the presence/absence of mathematical equations. The purpose of sketching this conceptual scaffold is to identify unknown entities, make predictions, and design experiments targeted at unanswered questions.

A cell by itself is a complete genetic and biochemical reactor holding all the information necessary to sustain life. It offers an ideal middle path between (extreme ends of) atomic interactions and whole organs. By creating a whole-cell model, it is at least theoretically possible to stretch out in either direction. Experimental biology has now reached a stage where future research will heavily depend on the *in silico* contribution. Though static representation of data has traditionally helped develop an overall perspective, it is the dynamic modeling that aids in better understanding of the cellular machinery (Table 1).

Broadly, whole-cell transactions may be classified into enzymatic and nonenzymatic processes. Enzymatic processes represent most of the metabolic events while nonenzymatic processes represent gene expression and regulation, signal transduction, and diffusion. In order to create a complete virtual cell, it is important to have provisions for DNA replication and repair, transcription and its regulation, translation, energy metabolism, metabolism, cell division, signaling pathways, cell membrane dynamics (ion channels, pump, nutrients), and intracellular molecular trafficking with appropriate mathematical representations (Table 2).

Tab. 1 Basics of map construction.

Type of representation	*Description*
Linear chain	Unidirectional flow
Branched chain	Two enzymes participate in one reaction, resulting in different products
Loops	Two branches unite forming an inherent dependency between them
Cycles	Larger loops comprising many intermediates

Tab. 2 Mathematical representation of cellular processes

Process	*Dominant phenomenon*	*Typical computational schemes*
Metabolism	Enzymatic reaction	DAE, S-Systems, FBA
Signal transduction	Molecular binding	DAE, stochastic, diffusion reaction
Gene expression	Molecular binding, polymerization, degradation	OOM, S-Systems, DAE, Boolean, stochastic, Bayesian, rule based
DNA replication	Molecular binding, polymerization	OOM, DAE
Cytoskeletal	Polymerization, depolymerization	DAE, particle dynamics
Cytoplasmic streaming	Streaming	Rheology, finite element method
Membrane transport	Osmotic pressure, membrane potential	DAE, electrophysiology

Notes: DAE: Differential algebraic equations; FBA: Flux balance analysis; OOM: Object-Oriented Modeling.

To accomplish the ''big picture,'' the data should not only be of good quality but should also be treated with intuitive mathematical representations that accurately describe life *in vivo*. It is noteworthy to mention that good data is more of an exception than rule! For modeling metabolic pathways, the data input typically consists of rate constants and concentrations. A metabolic pathway usually consists of a mixture of forward and reverse reactions (uni, bi, ter) of ordered/random types. The inhibitors may be intermediate compounds of the same pathway or external entities. The availability of good data makes the modeling process more or less a straightforward process, but often missing links have to be figured out due to incompleteness of information. Problems in doing so arise mostly due to numerical reasons – stiffness and parameter sensitivity. The main difference between data-to-model and model-to-data approaches is that in the former the starting material is substrate, enzyme, and modifier concentrations (for calculating the velocity curve), while in the latter, kinetic constants and velocity of reaction values are assumed. However, the difference between these two approaches sometimes blurs because in real life situations modeling often involves manual data fitting approaches to match an expected output or hypothesis. The major advantage of carrying out simulations is not only to study the system *per se* but also to extrapolate its behavior, even in the presence of a hypothetical condition, for example, a cell with many essential gene knockouts. Modeling, simulation, and analysis are therefore ideally positioned for integrating experimental knowledge into the *in silico* environment. In addition to demystifying nonintuitive phenomena, simulation lets us test experimentally unfeasible scenarios and can potentially reduce experimental costs. Although wet experiments are indispensable for the advancement of biological knowledge, *in silico* modeling can help shorten knowledge discovery. With the enormous computational power easily available, the challenging part in modeling is more conceptual than physical in nature.

The next section gives an overview of modeling tools, online resources, and databases that the modeling community often makes use of.

2 Biological Modeling and Simulation Tools

A number of promising tools are available for studying gene expression, regulation, and metabolic pathways (Tables 3 and 4). Below is a partial description of a few such tools.

2.1 DBSolve

URL: http://websites.ntl.com/~igor.goryanin/

DBsolve is an integrated development environment for metabolic, enzymatic, and receptor-ligand binding simulation. It is an ordinary differential equation (ODE)

Tab. 4 Tools for drawing pathways.

Name of the tool URL	*Target application*
Pathfinder http://bibiserv.techfak.uni-bielefeld.de/pathfinder/	Dynamic visualization of metabolic pathways represented as acyclic graphs
Electric Arc http://home.xnet.com/~selkovjr/ElectricArc/	CAD based, can be used to design abstract graphs to electronic circuits
Biopath http://biopath.fmi.uni-passau.de/index.html	Used for digitizing *Boehringer biochemical pathways*
Pathway Browser http://www-pr.informatik.uni-tuebingen.de/~eiglsper/pathways/	Visualization tool, XML-based, requires Java

based tool that incorporates stoichiometry of chemical reactions too. The main strength of DBsolve is the calculation of steady state, fitting, and optimization options.

2.2 Gepasi

URL: http://www.gepasi.org/

Gepasi simulates the steady state and time-course behavior of reactions over time and space based on stoichiometry and reaction kinetics values. The program is based on ordinary differential equations. It is a very useful tool for conducting metabolic control analysis and linear kinetic stability analysis leading to determination of the steady state of a system.

2.3 Jarnac

URL: http://www.cds.caltech.edu/~hsauro/Jarnac.htm

Jarnac is a cell modeling language for describing metabolic, signal transduction, and gene networks. It is linked to Jdesigner that the user interacts with for modeling a biochemical event.

2.4 Virtual Cell

URL: http://www.nrcam.uchc.edu/

Virtual Cell is a modeling tool that associates biochemical and electrophysiological data with microscopic image data describing subcellular locations. It is based on a strong mathematical foundation, and the results can be analyzed as images. Access to the Virtual Cell modeling software is via the Internet using a Java-based interface.

2.5 A-Cell

URL: http://www.fujixerox.co.jp/crc/cng/A-Cell/

A-Cell is a Windows-based graphical user interface (GUI) for the construction of biochemical reaction models. In addition, it has the capability of importing previously constructed models and combining them with the system.

2.6 BioQUEST

URL: http://omega.cc.umb.edu/~bwhite/ek.html

BioQUEST is a set of building blocks that run on the numerical simulation program ''Extend'' allowing the user to construct conduct time series analysis of biochemical reactions.

2.7 Dynafit

URL: http://www.biokin.com/

Dynafit is a software for simulating biochemical reactions. It also provides *ViraFit* for analysis of hepatitis C viral data, *BatchKi* (client server tool) for determination of tight-binding enzyme inhibition constants, and *PlateKi* (similar to Batchki) but runs as a stand-alone application.

2.8 ModelMaker

URL: http://www.modelkinetix.com/

ModelMaker allows the modeling of continuous and discontinuous functions and stiff and stochastic systems. It also provides optimization, minimization, Monte Carlo, and sensitivity analysis.

2.9 Metamodel

URL: http://bip.cnrs-mrs.fr/bip10/modeling.htm

MetaModel 3.0 is a DOS-based program for simulating simple biochemical reactions.

2.10 DMSS

URL: http://www.bio.cam.ac.uk/~mw263/ftp/doc/ISMB99.ps

Discrete Metabolic Simulation System (DMSS) does not employ kinetic parameters, stoichiometry matrices, or flux coefficients. Instead, the rate of a reaction is modeled on the basis of competing metabolite concentrations or metabolite affinities to enzymes including metabolite and enzyme concentrations.

2.11 E-Cell

URL: http://www.e-cell.org

E-Cell is a modeling and simulation environment. The basic concepts and applications of the E-Cell system are detailed in sections below.

3 The E-Cell System

3.1 Introduction

The raw material for biological complexity is an immense diversity in components and rules that are employed to create and sustain life. In order to understand the underlying complexity and engineer new systems, it is necessary to create an environment that can translate biology at the level of mathematics. In the early 1990s, the concept of *in silico* biology had just started appearing on the horizon but the scientific community was waiting for proof of the concept. Since none existed at that time, we decided to create one. After many trials and errors, a virtual baby called E-Cell was born.

E-Cell is a short form for Electronic Cell. It is a generic object–oriented environment for modeling and simulating molecular processes of the whole cell in user-definable models, equipped with graphical interfaces that allow observation and interaction. The E-Cell modeling approach links diverse cellular processes such as gene expression, signaling, and metabolism, to form a virtual cell framework. Using E-Cell it is possible to create a model and also translate this model into a simulation environment through mathematical equations. More precisely, however, it is a generic system for constructing object models of the cells that can (optionally) emulate the behavior of numeric equation solvers.

In October 1996, the E-Cell project was started at Keio University, Japan. The first working version of E-Cell was ready within three months and the first virtual cell (*Mycoplasma genitalium*) was developed within a year. On March 2001, the beta version 1.0 of the software was publicly released under open source, and new GUI and peripheral software tools were added. Currently, E-Cell is celebrating its third birthday. Version 1.0 and 3.0 are developed for the Linux environment and version 2.0 for Windows. C++ is used for the components in which runtime efficiency, coding strictness, and flexibility are critical. Python is an ideal language for the other user-side

Tab. 5 E-Cell versions.

E-Cell 1.0 (Linux)	*E-Cell 2.0 (Windows)*	*E-Cell 3.0 (Linux)*
Entire E-Cell application including GUI written in C++	Uses a cocktail of C++, Perl, Cygwin, Java	Core portions (libecs, libemc) and simulation objects (reactors, substances, steppers) written in C++
Peripheral programs (er2eri, ss2er, rd2ch, etc.) written in Perl, Python, and yacc/lex		Most other components, including front end, written in Python

Notes: ML = mailing list.

components, where productivity and readability are demanded (Table 5). E-Cell is an open source project. The entire documentation with source code is available from http://www.bioinformatics.org/E-Cell/. Bioinformatics.org is a nonprofit, academe-based organization committed to opening access to bioinformatics research projects. The publicly available mailing lists have been detailed in Table 6. Since E-Cell is an open source project, the expected third-party contribution includes algorithm modules, GUIs, new language bindings, and mathematical analysis modules. E-Cell (version 3.0) is a highly modularized software that can easily be extended by writing plug-ins.

3.2 Architecture of E-Cell

The description here mainly refers to E-Cell version 1.0. The E-Cell software constructs object models equivalent to a cell system or a part of a cell system employing Structured Substance-Reactor model (SRM). In the SRM, the objects belong to one of the three fundamental object types (Primitives): Substance, Reactor, or System. The Substances represent amounts of a molecular species or other state variables. The Reactors represent cellular phenomena that result in change in the amount or value of the molecular species or the state variables. The Systems are used as

containers for the Primitives representing functional and/or physical compartments. In E-Cell 1.0, a cell model description is composed of two parts: definition of subclasses of the Primitives (mainly of the Reactor) and a rule file. The rule file contains information of (1) a list of the three Primitive objects in the model, (2) relationships among the objects (e.g. stoichiometry of reactions), and (3) parameter values for the objects (e.g. rate constants).

3.2.1 Elements of the Control Panel

The substance window shows the quantity of a selected substance. It also allows the user to alter the quantity at will during the simulation process. The reactor window displays the activity of a selected reaction. The activity of a reaction is defined as the amount of product produced per second in the reaction process. Tracers are windows that plot the concentration of substances with time (Fig. 1).

3.2.2 Elements of the E-Cell Model

In the E-Cell system, substance is a substrate, product, catalyst, or an ion that affects a reaction. Typically, substances include proteins, protein complexes, DNA (genes), RNA, and small molecules. The total number of molecules involved in a reaction is defined as *quantity* while *concentration* describes the amount of substance present in a reaction space (in moles per liter). In the E-Cell, the quantity of a substance equals Avagadro's number times concentration times volume. The E-Cell simulation software uses the number of molecules in a sample to trace a reaction and automatically converts concentration into quantity. The spreadsheet data file needs to be converted to .er text format. It is possible to use macros in the .er file to model complicated systems with ease. In E-Cell 3.0, .er and .eri file formats are no longer used. It uses an XML-based E-Cell model description language. The E-Cell system extracts quantitative information from the rule file, links it up with the equations described in reactors, and plots the velocity curve on tracers.

A special characteristic of E-Cell is the accumulator. The Reserve Accumulator (the default feature) is used when

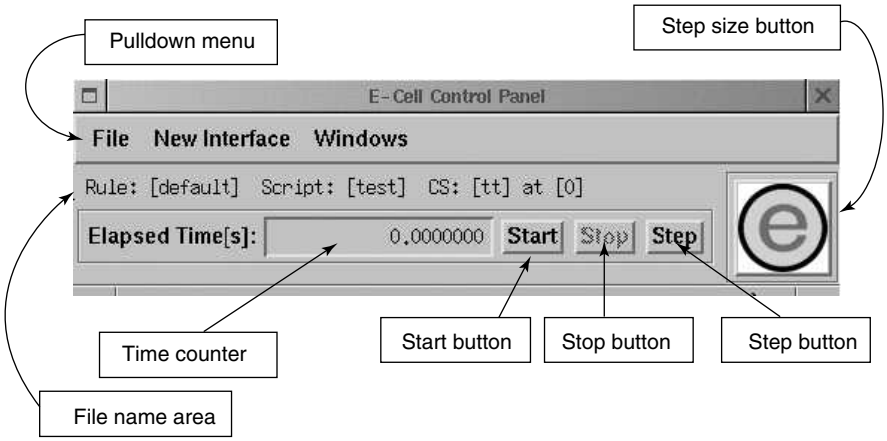

Fig. 1 Elements of the control panel.

decimal fractions are unimportant, for example, when representing an individual cell. However, the Simple Accumulator is used in situations in which the floating-point value is crucial to the interpretation of the results, for example, if the number of molecules is very large or if the simulation represents an ''average cell'' among a large number of cells. The MonteCarlo Accumulator is used if the simulation requires a high degree of precision in statistical analysis.

3.3 Features of E-Cell 2.0

Recently, Mitsui Knowledge Industry has released the Windows version of E-Cell (ver 2.0). The E-Cell 2.0 is very similar to the E-Cell 1.0 except that the virtual memory function (to show the concentration in the tracer for a long time) is not implemented for now. However, the E-Cell data file contains time, mean value, maximum value, and minimum value as against time and value output of version 1.0.

To run this version, the following supporting software is required:

*m4.exe distributed in Cygwin<http://sources.redhat.com/cygwin/> *Java runtime environment (http://java.sun.com/products/jdk/1.2/), *Perl (http://www.perl.com/pub/a/language/info/software.html), and *C++ (http://www.borland.com/bcppbuilder/freecompiler/)

3.4 Features of E-Cell 3.0

E-Cell 3.0 is currently being developed with an aim of providing the cell simulation community a generic and high performance software environment. It is also Linux-based and has a geometry information interface. It will integrate any sets of different simulation algorithms including the Variable-Process model, differential equation–based, diffusion reaction, and particle dynamics–based approaches. One of the main highlights of the software would be integration of subsystems with different timescales. E-Cell 3.0 allows many components, driven by different simulation algorithms and different timescales, to coexist in the simulation by employing a discrete-event worldview as its fundamental formalism.

The core simulation software of E-Cell 3.0 is a set of extension modules for the Python language interpreter, written in C++/C/Python. It consists of a libecs cell modeling toolkit, an E-Cell microcore (EMC) layer, a Python language binding (PyECS), and other peripheral Python modules. Libecs (code name: Koyurugi) is a generic object-oriented C++ class library for constructing various object-based cell models. One of the special features of Koyurugi is that the constructed cell models themselves work as simulation engines. The E-Cell Micro Core defines interfaces and implementations of the Simulator class, which provides a simple application programming interface (API) of the Koyurugi class library. PyECS is basically a Python binding of the EMC. Libecs, EMC, and a main portion of PyECS are written in C++ language.

3.5 Advantages of the E-Cell System

1. The E-Cell architecture allows users to easily add components to the E-Cell simulation software in order to address individual modeling needs.
2. E-Cell can accommodate many different kinds of simulations rather than following one specific methodology, that is, it can simulate deterministic

or stochastic models, either alone or together. Thus, users are able to model biological systems according to their characteristics, and incorporate diverse methods in the same model. In the first version of E-Cell, this is enabled by Reactors. Reactors are coded in C++, thereby offering users a huge bandwidth for simulating a large variety of reactions. In E-Cell 3.0, we will be able to create new types of Reactors, Substances, and Systems (and Stepper) allowing more flexibility. For example, users will be able to define integration method.

3. E-Cell is custom-made even for people with little/no programming knowledge.
4. E-Cell offers efficient data management through Rule files. This is particularly useful when you have large amounts of data.

3.6 Limitations of the E-Cell System

1. E-Cell 1.0 and 2.0 do not have sophisticated concentration gradient model/simulated 3-D structures and molecular dynamics at the moment. However, this constraint has been overcome in E-Cell 3.0.
2. Ordinary differential equations and algebraic equations can only be calculated explicitly. However, in most cases, users can make adjustments to components to incorporate other calculation methods (such as incorporating a library within the reactor that allows implicit calculation of ODEs).

3.7 E-Cell with 127 Genes

The E-Cell with 127 genes is a hypothetical cell that contains the minimum gene set for survival (Fig. 2). We borrowed the genomic construction from *M. genitalium* to build our first virtual cell to conduct what we call ''minimum cellular metabolism.'' This model takes up glucose from the culture medium using a phosphotransferase system, generates ATP by catabolizing glucose to lactate through glycolysis and

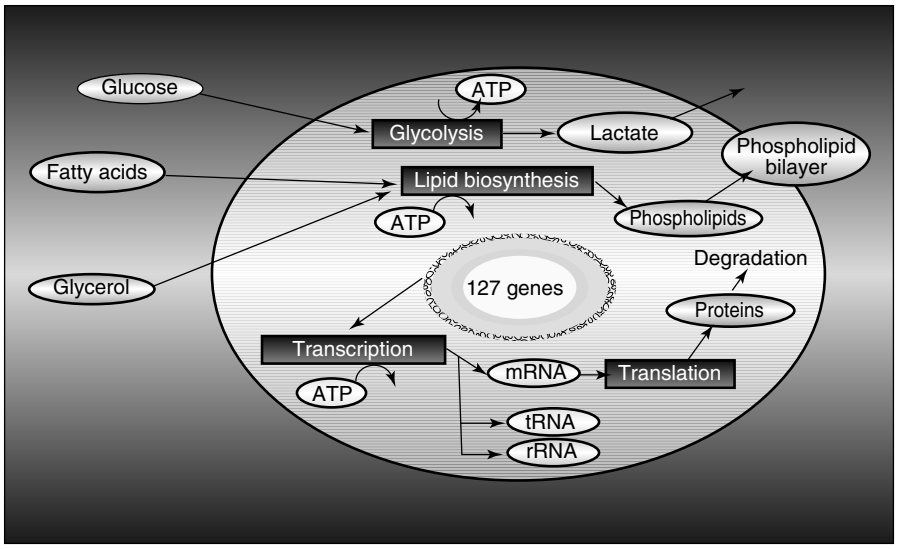

Fig. 2 E-Cell with 127 genes.

fermentation, and exports lactate out of the cell. Enzymes and substrates are spontaneously synthesized and degraded over time to sustain ''life''. The protein synthesis is implemented by modeling the molecules necessary for transcription and translation, namely, RNA polymerase, ribosomal subunits, rRNAs, tRNAs, and tRNA ligases. The cell also takes up glycerol and fatty acids, and produces phosphatidyl glycerol for membrane structure using a phospholipid biosynthesis pathway. The model cell is ''self-supporting'', but not capable of proliferating; the cell does not have pathways for DNA replication or the cell cycle. The *Mycoplasma* ammunition we used was formed of genes involved in glycolysis (9), lactate fermentation (1), phospholipid biosynthesis (4), phosphotransferase system (2), glycerol uptake (1), RNA polymerase (6), amino acid metabolism (2), ribosomal L-subunit (30), ribosomal S-subunit (19), rRNA (2), tRNA (20), tRNA ligase (19), initiation factor (4), and elongation factor (1). Overall, we ended up with 98 protein coding genes and 22 RNA coding genes. The rest (7 genes) were imported from other sources. All this was spread out into 495 reaction rules that modeled enzymatic reactions responsible for increasing/decreasing substrate/product quantities, multisubstrate complex formation, transportations of substances, and stochastic processes, for example, transcriptional factors binding factor binding to a specific site of the chromosome.

Mycoplasma genitalium was chosen for constructing a virtual cell with the minimum number of genes for survival, because it has the smallest known genome. Its genomic sequence (580 kb) was determined in 1995. We abstracted *M. genitalium's* gene set to accommodate only those genes that were required for the bare, essential cellular metabolism. At the time of developing the first version of E-Cell, 120 genes from *M. genitalium* were identified and well documented. However, in order to successfully hand-construct a self-sustaining cell, this number just fell short by 7. The shortage was made up by roping in genes from ''external sources'' – 4 for phospholipid biosynthesis, 1 each for nucleoside phosphate kinase and nucleoside diphosphate kinase, and 1 for tRNA ligase. At that time, the phospholipid biosynthesis and a few other pathways in *M. genitalium* were not well characterized. The information on the kinetic properties of genes and proteins was mostly obtained from the KEGG and BioCyc (previously called EcoCyc) databases.

3.8 Applications of the E-Cell System

The E-Cell with 127 genes predicted for the first time a sudden sharp increase in the ATP level in a glucose-starved cell followed by the equally sharp decrease of ATP. Though the second event was expected, the first one was a big surprise and was later confirmed experimentally. This anomalous situation was explained by the fact that though ATP production was stalled by cutting off glucose levels, it took the cell a little while to consume the intermediates for ATP production, thus, resulting in a sudden increase of ATP. This example demonstrates the potential of *in silico* modeling in generating new information. Furthermore, recent pointers indicate a paradigm shift from experimental biology to *in silico* biology.

Overall, the E-Cell has applications in the following areas:

1. *Metabolic requirements*: The assessment of the metabolic requirements of the

cell is an area E-Cell can successfully address. At present, *M. genitalium* is grown in a complex medium containing several chemically undefined components including fetal bovine serum and also yeast and beef extracts. By combining knowledge of metabolic enzymes present in the cell with information concerning protein transporters of metabolites across the cell membrane, it should be possible, by using the E-Cell model, to evaluate whether a particular defined medium can support growth.

2. *Gene expression*: E-Cell software can be used to decipher gene regulatory networks. We plan to use *M. genitalium* to achieve this objective.

3. *Minimal gene set*: The self-sustaining E-Cell will be further extended to define the minimal set of genes required for a self-replicating cell under a specific set of laboratory conditions.

4. *Clinical applications*: We are currently exploring clinical applications of the E-Cell, for example; diabetes, red blood cell enzyme deficiencies, and so on (see Sect. 3.9).

3.9 Simulation of Red Cell Enzyme Deficiencies

Glucose-6-phosphate dehydrogenase (G6PD) is a key enzyme that produces NADPH in the pentose phosphate pathway (Fig. 3). G6PD converts glucose-6-phosphoric acid into 6-phosphogluconо-1,5-lactone, and generates NADP, which

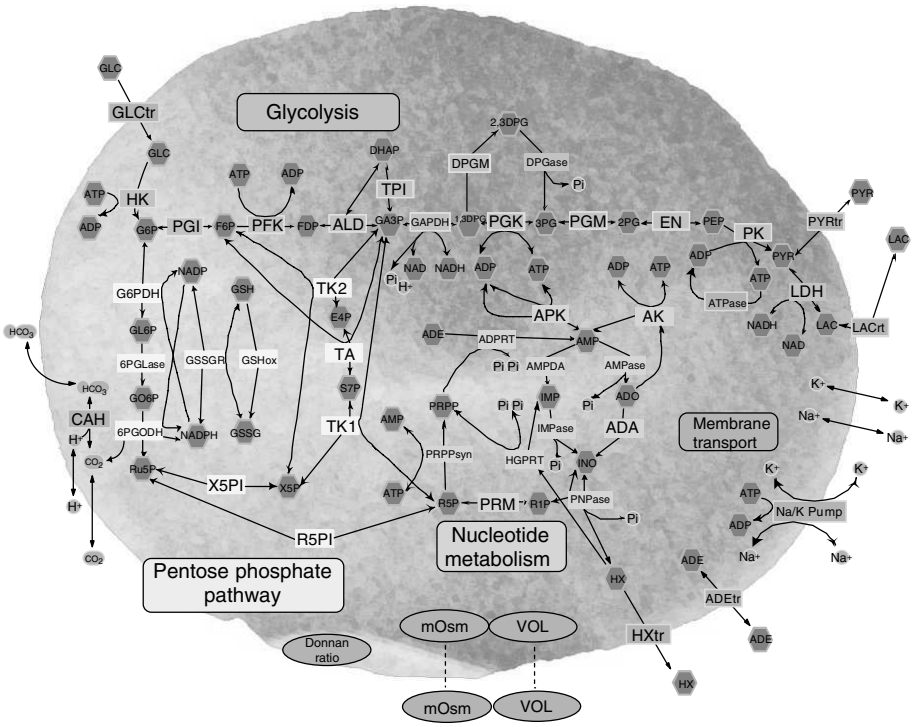

Fig. 3 Whole erythrocyte model.

is then metabolized into ribulose-5-phosphoric acid via 6-phosphogluconic acid generating NADPH in the process. A major function of GSH in the erythrocyte is to eliminate superoxide anions and organic hydroperoxides. Peroxides are eliminated through the action of glutathione peroxidase, yielding oxidized glutathione (GSSG).

We have implemented the G6PD deficiency into the E-Cell model and modified the kinetic parameters in accordance with the biochemical environment of mutant cells from patients reporting this deficiency. The simulation experiments were carried out with steady state concentrations corresponding to those of the normal erythrocyte. Sequential changes in the quantity of NADPH, GSH, and ATP were observed in the simulation experiments. However, the longevity of our computer model estimated by the concentration of ATP turned out to be much shorter than that of the real erythrocyte with G6PD deficiency. This difference was, presumably, due to the lack of pathways producing GSH and the export system of GSSG. After modification, the longevity of the cell and the GSH/GSSG ratio was found to have increased. Our result indicates that these pathways partially compensate for the reduction of GSH and have a role in easing anemia, a condition of G6PD deficiency. This result can be a good explanation for the fact that G6PD deficiency is the most common cause of anemia. If the deficiency with these compensation pathways has no severe disadvantage for survival, it would spread through the population. When the activity of G6PD decreases, the activity of 6-phosphogluconate dehydrogenase increases, compensating for the reduced production of NADPH. However, because either 6-phosphogluconono-1,5-lactone was not supplied or because G6P was deficient, the 6-phosphogluconic acid supply was quickly exhausted and the production of NADPH was stopped. The amount of NADPH started to reduce gradually and was soon exhausted. Subsequently, GSH started to decrease and was soon completely converted into GSSG. Finally, the cells worsened in their metabolic performance and exhausted all the ATP because of the inhibition of rate-determining enzymes (due to low GSH/GSSG). This model of G6PD deficiency correlates well with the clinical situation and can be a test bed for extending the model to other human erythrocyte metabolic disorders (Fig. 4). We are also trying to reconstruct the erythrocyte model with pyruvate kinase (PK) deficiency. On creating an *in silico* model for PK deficiency, the ATP production rate was found to decrease proportionately leading to eventual elimination from the system. Simultaneously, an increase in the concentration of 2-phosphogrycerate, 3-phosphoglycerate, and phosphoenolpyruvate was observed, which is in agreement with the clinical presentation of the PK phenotype.

4 Concluding Remarks

In order to understand the *whole* we must model the *whole*, because a cell is basically systems biology, by default. Given the enormous complexity and data generated by genome, proteome, transcriptome, and metabolome, computer simulations are indispensable for future biological research. Whether or not it is feasible to construct a computer model of a whole living cell is still an open question. Although no attempts were made toward whole-cell modeling until the late

Effect on ATP

3PG: 3-Phosphoglycerate, 2PG: 2-Phospho-glycerate
PEP: Phosphoenolpyruvate, LACi: Lactate

Fig. 4 Simulation of red cell deficiency.

1990s, the importance of computer simulation of cellular metabolism has been realized since the 1980s. Various cellular transactions like gene expression, cell cycle, signal transduction, and metabolic pathways have been modeled and simulated independently. However, to understand the cross talk among these seemingly ''self-regulating systems'', it is necessary to construct an integrated model of the cell. One of the major problems in constructing large-scale models is a lack of quantitative data. Most of the biological knowledge is qualitative (in the form of pathway maps). The quantitative data available in the published literature is often noisy and not well suited for simulations. Thus, a major challenge is to collect a large amount of highly accurate and, preferably, time series data, construct quantitative models, and train the models with more wet-bench results till simulation matches real life biology. To achieve this objective, we not only need good data but also a novel computational and software engineering approach. This is the biology of the twenty-first century.

Keywords

Chemical Electric and Magnetic Field Effects
The consequences of the primary field effects on ions and dipoles, which cause the rate and equilibrium constants of reactive chemical processes and phase transitions to depend on the electric field strength and, to a weaker extent, on the magnetic flux density.

Cooperativity
A mechanism for the simultaneous state transition of a cluster or domain of strongly coupled molecules in a narrow field-strength range.

Electric and Magnetic Field Strength
Measures of the force on electric charges and electric and magnetic dipoles, respectively. The targets are either freely mobile or are fixed ionic and magnetic groups of larger macromolecules.

Interfacial Electric Polarization
Field-induced ion accumulation at interfaces of media with different dielectric constants, leading to ionic charging up of membranes and to large induced transmembrane voltages by small external fields.

Magnetic Induction of Electric Fields
The main effect of time-varying magnetic fields, causing ionic (AC) currents and dipolar displacement currents, both of which interfere with chemical reactivity.

Magnetosomes
Small elongated magnetite (Fe_3O_4, Fe_3S_4) organelles that, in magnetobacteria, serve for geomagnetic field sensing and direction finding and are also found in cells of higher organisms.

Electric field reception (*E*) and magnetic field reception (*B*) are defined as the mutual interaction of external fields with the relatively high internal fields of the ionic and the (electric and magnetic, respectively) dipolar components including the cellular magnetosomes involved in sensory processes. The natural *E* fields are particularly apparent in the electrophysiological function of nerves. Physicochemically, the *E* and *B* fields primarily act on charges, changing their positions and motional states. As a consequence, the extent and the rate of chemical reactions, conformational changes, and phase transitions of the field-receiving molecules are dependent on the strength of the *E* and *B* fields. Although there are *always* finite chemical shifts in rate and equilibrium constants, weak external fields require amplification processes (e.g. interfacial polarization of larger particles and cooperativity in domain structures).

1 Concepts

In biology, electric and magnetic field reception is commonly associated with sensory processes. The electric fish have developed special electric organs to sense the environment for orientation, navigation, and food search. Electric eels and torpedo fish utilize large electric discharge organs for prey capture. Magnetobacteria contain small magnetite (Fe_3O_4, Fe_3S_4) organelles that serve for direction finding in the earth's magnetic field. Such magnetosomes are also found in higher organisms. It is important to note that biological weak-field reception and behavioral responses are intimately coupled with the nervous system. The receptive and sensing fields of the biosphere are either static (DC) fields or short field pulses of 0.1 to 1 ms duration with low pulse frequencies ($\leq$3 kHz), producing direct currents (DC) or current pulses.

Electrotechnologically, manmade electric and magnetic field devices have become indispensable tools of life. In medicine, in particular, we observe a growing application of the electric and magnetic field apparatus for both diagnostic and therapeutic purposes. On the other hand, it is not yet clear whether the technical fields of power transmission lines and electrical household devices bear potential health risks, even under normal safety conditions. To estimate the possible beneficial or negative effects, it is necessary to understand the physical and chemical interaction mechanisms of electric and magnetic field reception.

Generally, electric and magnetic fields act as forces on charges: electrolyte ions and fixed ionic groups, as well as free electric and magnetic dipolar molecules and fixed dipolar groups of macromolecules, including membrane lipids and cellular magnetosomes. As a consequence of these primary field effects, reactive chemical interactions are dependent on the electric field strength $\mathbf{E}$ (Vm^{-1}) and, to a much weaker extent, on the magnetic field strength $\mathbf{H}$ (Am^{-1}).

1.1 Natural Fields

All life processes have evolved in the natural electric and magnetic force fields of the earth. These geofields are quasi-static or only slowly time-varying. Compared to

possible technical fields, they are classified as weak. The average geoelectric field strength is $|\mathbf{E}_0| \approx 200\ \mathrm{Vm}^{-1}$, the average geomagnetic flux density $|\mathbf{B}_0| = \mu_0\mu|\mathbf{H}_0| \approx 50\ \mu\mathrm{T}$, where $\mu_0 = 1.256 \times 10^{-6}$ Vs/(Am) is the vacuum permeability and the magnetic susceptibility $\chi_{\mathrm{ma}} = \mu - 1$.

Even in its lowest forms, life makes use of electric and magnetic field effects, most obviously, on the microscopic level, in the rapid signal transmission of neurons, involving, in particular, the gated transport of Na^+, K^+, Ca^{2+}, and Cl^--ions.

1.2 Definition of Field Reception

In molecular biology, the term *field reception* appears meaningful only if it comprises more than just the direct interactions of the force fields (and their spatial gradients) with molecules, changing their positional and motional state. An adequate definition of this term must specify at least the next biochemical or biophysical process following the preceding direct force effects. Thus, field reception indispensably includes field effects on the reactive interactions, on the molecular orientations, and on the transport processes of the "field-receiving"ions and electric and magnetic dipoles. Moreover, amplification mechanisms for both small external fields and for locally small chemical shifts are important features of the molecular characterization of field reception.

Briefly, the effects of external E and B fields may be summarized as a cascade of mutual interaction steps:

$$(E, B)_{\mathrm{ext}} \longleftrightarrow (E, B)_{\mathrm{int}} \longleftrightarrow \left| \begin{array}{l} \Delta c,\ \Delta\varphi_{\mathrm{m}} \\ \Delta K/K_0,\ \Delta\beta/\beta_0 \\ \Delta k/k_0 \end{array} \right|$$

The primary step in field reception (and emission) is the mutual interference of the external E and B fields, $(E, B)_{\mathrm{ext}}$, with the local (body and cell) internal fields $(E, B)_{\mathrm{int}}$, provided the external static and low-frequency E fields can penetrate the systems, for instance, via direct (metal) electrode contact. The subsequent steps may occur in parallel (Fig. 1): (1) Mutual changes in electrolyte flows (resulting in local ion concentration changes Δc) and in the internal fields, including the relatively very strong E fields of the cell membranes ($E_{\mathrm{m}}10^3$–$10^4\ \mathrm{kVm}^{-1}$) corresponding to electric membrane potential differences on the order of $|\Delta\varphi_{\mathrm{m}}| = 0.01$ to 0.2 V and (2) field-induced changes of ligand-binding processes, of conformational transitions, and of cooperative domain phase transitions (e.g. in membranes).

Theoretically, the field-induced changes may be quantified as relative changes $(\Delta K/K_0, \Delta\beta/\beta_0, \Delta k/k_0)$ in the equilibrium constants (K), in the extents of ligand binding and of transitions (β), and in the rate coefficients (k).

2 Field and Molecular Motion

2.1 Internal and External Fields

To understand the effects of external fields on freely mobile ions, on dipolar charge pairs, and on "fixed" ionic or dipolar groups of larger molecules, it is important to realize that these ions and dipoles are themselves the sources of local fields, which, near the charges, have an impressively high field strength (on the order of $3000\ \mathrm{kVm}^{-1}$ at body temperature). The local electric fields are largely screened by mobile counterions (ionic atmosphere) or

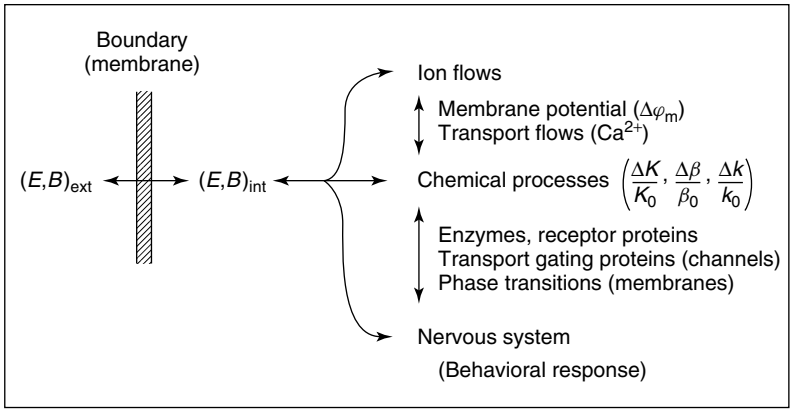

Fig. 1 Interaction scheme for electric (*E*) and magnetic (*B*) field reception. Direct current, static, and low-frequency external *E* fields ($\mathbf{E}_{ext}$) induce noticeable changes in the body's internal fields only if there is direct contact (e.g. via metal electrodes). The surfaces of conducting matter represent no barriers for high-frequency *E* fields and all magnetic fields. The $(\mathbf{E}, \mathbf{B})_{ext}$-induced changes in $(\mathbf{E}, \mathbf{B})_{int}$ modulate ion flows and chemical processes, in particular, in and on membranes. Weak-field reception and emission by special skin organs always involves the nervous system.

by neutralizing ion pairing. The motion of charges in moving fluids (like the electrolyte ions in the blood) always produces magnetic fields that in turn give rise to electric potential gradients.

External electric and magnetic fields have to compete with the internal biofields. The **E** (DC) fields and the low-frequency (LF) alternating (AC) **E** fields of the air are effectively reduced by conducting material like the skin of the human body. At low frequencies ($\leq$3 kHz), the internally induced electric fields in conductive bodies are therefore extremely small. On the other hand, external magnetic fields are not screened; they permeate bodies. The main effect of time-varying magnetic fields is the induction of time-varying electric fields that cause dissipative ionic (AC) currents as well as electric dipolar displacement (capacitive) currents.

On the level of cells and organelles, the dielectric material of the plasma membrane has condensor properties for the storage of electric energy. External fields cause changes in the ion accumulations at the membrane–solution interfaces. Externally induced interfacial polarizations can lead to enormous amplification of the transmembrane electric field, which in turn can appreciably affect the reactions of membrane proteins and the various transmembrane transport phenomena.

2.2 Thermal Motion

Another important aspect is that the electric and magnetic interaction energy $\Delta_r G_{(F)}$ must compete with the randomizing thermal motion of the species. The thermal noise energy is given by $k_B T$, or on a molar scale, by RT, where k_B is the Boltzmann constant, $R = N_A \cdot k_B$ is the gas constant, N_A the Avogadro constant, and T is the thermodynamic (Kelvin) temperature. In order to be relevant, the electric and magnetic field effects

must emerge from thermal noise and the normal concentration fluctuations.

2.3 Freely Mobile Charges

The **E** and **B** fields are a measure of the respective force line densities. **E** and **B** are defined by the electric and magnetic forces $\mathbf{F}_{el}$ and $\mathbf{F}_{ma}$ exerted on the charge q respectively changing the velocity **v** of free charges and the position of fixed and dipolar charge pairs.

The direction of change is globally given by the charge number z_i (with sign) of the ion or ionic group i such that $q_i = z_i e_o$, where $e_o = 1.6 \times 10^{-19}$ As is the positive elementary charge, and by the drift speed,

$$\mathbf{v}_i = \frac{z_i}{|z_i|} u_i \mathbf{E} \qquad (1)$$

where u_i is the electric mobility. The Coulomb law $\mathbf{F}_{el} = q\mathbf{E}$ and the Lorentz law $\mathbf{F}_{ma} = q(\mathbf{v} \times \mathbf{B})$ yield the total force on q:

$$\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}) \qquad (2)$$

The vector cross product $\mathbf{v} \times \mathbf{B} = |\mathbf{v}||\mathbf{B}| \sin\theta$, where θ is the angle between the vectors **v** and **B**, describes the circular motion of a charge around the **B** lines. Note that $\mathbf{F}_{ma}$ is maximal if **v** and **B** are at right angle and $\mathbf{F}_{ma} = 0$ if **v** and **B** are parallel or if the charge is fixed ($\mathbf{v} = 0$).

2.4 Dipole Orientation and Dipolophoresis

Electric and magnetic dipoles are oriented in homogeneous **E** and **B** fields respectively. The fields exert a torque against the thermal energy $k_B T$. In spatially inhomogeneous fields, dipoles not only rotate into the field direction but also move translationally in the direction of higher or lower field strengths (dipolophoresis, sometimes inappropriately called dielectrophoresis). The total force **F**(r) exerted by, say, a radially inhomogeneous field is given by the dot products

$$\mathbf{F}(\mathrm{r}) = \mathrm{m}_{el} \cdot \frac{\partial \mathbf{E}}{\partial \mathrm{r}} + \mathrm{m}_{ma} \cdot \frac{\partial \mathbf{B}}{\partial \mathrm{r}} \qquad (3)$$

where the partial space derivatives are a measure of the inhomogeneity of the respective fields.

2.5 Electric Currents

The motions of charges and dipoles may be measured as ohmic and capacitive currents. The current density **J** (A/m^2) is related to the field strength by

$$\mathbf{J} = \kappa \cdot \mathbf{E} + \frac{\partial \mathbf{D}}{\partial \mathrm{t}} \qquad (4)$$

where κ is the ionic conductivity of the medium and $\mathbf{D} = \varepsilon_0 \varepsilon \mathbf{E}$ is the dielectric displacement vector (covering dipole reorientations), where $\varepsilon_0 = 8.854 \times 10^{-12}$ As/(Vm) is the vacuum permittivity and ε is the (relative) dielectric constant of the homogeneous medium.

In polyelectrolytes like DNA and on polyionic membrane surfaces, an external field can cause displacements of the counterion atmospheres, thereby inducing stationary "ionic flow-dipoles" having appreciably high dipole moments.

The circular-current density vector induced by a homogeneous magnetic field acting on moving charges q_i ($\mathbf{v}_i$) is given by the sum of all ion contributions

$$\mathbf{J} = \kappa \mathbf{E}_{ind} = \kappa \Sigma_i (-\mathbf{v}_i \times \mathbf{B}) \qquad (5)$$

Time-varying magnetic fields induce ion flows by magnetic induction. The voltage (U_{ind}) induced around a closed path of length $\ell = \int \mathrm{d}\mathbf{s}$, where d**s** is a differential

path element, is given by

$$U_{\mathrm{ind}} = \oint \mathbf{E}\,\mathrm{d}\ell = -\iint \left(\frac{\partial \mathbf{B}}{\partial \mathrm{t}}\right) \mathrm{d}\mathbf{s} \quad (6)$$

where $\partial\mathbf{B}/\partial\mathrm{t}$ is the time derivative of **B**. Since the dot product $(\partial\mathbf{B}/\partial\mathrm{t}) \cdot \mathrm{d}\mathbf{s} = (\partial|\mathbf{B}|/\partial\mathrm{t})\mathrm{d}|\mathbf{s}| \cos\theta$, U_{ind} is maximal if **B** is perpendicular to the path (surface), that is, parallel to **s**. The magnitude of the **E**(t) field of frequency f at a perpendicular distance **r** from the center of a path around the **B** direction is $|\mathbf{E}_{\mathrm{ind}}| = \pi \mathrm{f}|\mathbf{B}||\mathbf{r}|$ and the current density $|\mathrm{J}| = \kappa\pi \mathrm{f}|\mathrm{B}||\mathrm{r}|$ increases linearly with frequency. Magnetically induced currents are generally about 10^3 times larger than those induced directly by external electric fields $\mathbf{E}_0(f)$.

3 Chemical Reaction Equilibria

In biochemistry, we frequently encounter ligand (L)-induced changes in the conformation of macromolecular binding sites (B). This induced fit is described by the scheme

$$\mathrm{L} + \mathrm{B} \overset{(K_1)}{\rightleftharpoons} \mathrm{LB} \overset{(K_2)}{\rightleftharpoons} \mathrm{LB}' \quad (7)$$

where the conformational transition $\mathrm{B} \rightleftharpoons \mathrm{B}'$ is inherent. The physically more realistic reaction scheme comprises two binding steps and two structural transitions:

$$\begin{array}{ccc} & (K_1) & \\ \mathrm{L} + \mathrm{B} & \rightleftharpoons & \mathrm{LB} \\ (K_4) \Big\| & & \Big\| (K_2) \\ \mathrm{L} + \mathrm{B}' & \rightleftharpoons & \mathrm{LB}' \\ & (K_3) & \end{array} \quad (8)$$

The individual equilibrium constants $K_1 = [\mathrm{L}][\mathrm{B}]/[\mathrm{LB}]$, $K_3 = [\mathrm{L}][\mathrm{B}']/[\mathrm{LB}']$ and $K_2 = [\mathrm{LB}']/[\mathrm{LB}]$, $K_4 = [\mathrm{B}']/[\mathrm{B}]$, where the brackets denote molar concentrations, are related by $K_1/K_3 = K_2/K_4$.

The apparent equilibrium constants K, defined as equilibrium concentration ratios, may vary with concentration and with the ionic strength because of the screening effects of ions and other nonreactive interactions. When a reaction is written in the suggestive form $0 = \Sigma_{\mathrm{i}} \nu_{\mathrm{i}} \mathrm{J}$, where ν_{j} is the stoichiometric coefficient of the reaction partner J (positive for a product, negative for an educt), the "really constant" thermodynamic equilibrium constant K° is defined as the equilibrium activity ratio:

$$K^{\circ} = \Pi a_{\mathrm{j}}{}^{\nu_{\mathrm{j}}} = |K| \cdot Y = \exp\left(\frac{-\Delta_{\mathrm{r}}\hat{\mathrm{G}}^{\circ}}{RT}\right), \quad (9)$$

where $\Delta_{\mathrm{r}}\hat{\mathrm{G}}^{\circ}$ is the standard value of the transformed Gibbs reaction energy. See Eq. (15).

The thermodynamic activity a_{j} is a dimensionless quantity expressed as $a_{\mathrm{j}} = |c_{\mathrm{j}}|\gamma_{\mathrm{j}}$, where $|c_{\mathrm{j}}|$ is the numerical value of the concentration c_{j} and γ_{j} is the thermodynamic activity coefficient. Hence, from $K^{\circ} = |K|Y$, we see that $K = \Pi c_{\mathrm{j}}{}^{\nu_{\mathrm{j}}}$ and $Y = \Pi \gamma_{\mathrm{j}}{}^{\nu_{\mathrm{j}}}$. Note that Eq. (9) is used to relate experimental data via K° to the reaction energetics.

3.1 Dipole Reaction

For the general analysis of field-induced changes, the scheme $0 = \Sigma_{\mathrm{j}} \nu_{\mathrm{j}} \mathrm{J}$ is specified in terms of reactive educts J_{r} and products J_{p} according to

$$\Sigma_{\mathrm{r}} |\nu_{\mathrm{r}}| \mathrm{J}_{\mathrm{r}} \underset{k_{\mathrm{p}}}{\overset{k_{\mathrm{r}}}{\rightleftharpoons}} \Sigma_{\mathrm{p}} \nu_{\mathrm{p}} \mathrm{J}_{\mathrm{p}} \quad (10)$$

where k_{r} and k_{p} are the rate coefficients for the forward and backward reaction steps

respectively. The molar reaction dipole moment $\Delta_r M^{\circ\!\!\!-}$ relevant for field effects is defined as the difference

$$\Delta_r M^{\circ\!\!\!-} = M_p - M_r = N_A \langle \Delta_r m \rangle \quad (11)$$

where M_p and M_r are the average molar moments of the products and reactants respectively. The molecular reaction average $\langle \Delta_r m \rangle$ is given by the individual contributions of the reactant and product molecules:

$$\langle \Delta_r m \rangle = \Sigma_r |\nu_r| \|\mathbf{m}_r| \langle \cos\theta \rangle - \Sigma_p \nu_p |\mathbf{m}_p| \langle \cos\theta \rangle \quad (12)$$

The brackets $\langle\rangle$ denote orientational averages and θ is the angle between the dipolar axis of a molecule J and the field direction.

Introducing now $F = F_{(E,B)} = |\mathbf{E}|$ or, in the other case, $F = F_{(E,B)} = |\mathbf{B}|$ for the amount of the electric field strength vector $\mathbf{E}$ and that of the magnetic flux density vector $\mathbf{B}$ respectively, the general expression of the (isothermal, isobaric) field-induced change of $K^{\circ\!\!\!-} = \exp[-\Delta_r \hat{G}^{\circ\!\!\!-}/RT]$, see Eq. (9), is given by a van 't Hoff-like expression:

$$\left(\frac{\partial \ln K^{\circ\!\!\!-}}{\partial F}\right)_{p,T} = \frac{\Delta_r M^{\circ\!\!\!-}}{RT} \quad (13)$$

For $F = |\mathbf{E}|$, $\langle \Delta_r m \rangle$ is the electric reaction moment; for $F = |\mathbf{B}|$, $\langle \Delta_r m \rangle$ refers to the molar difference in the magnetic moments. Integration of Eq. (13) yields

$$K^{\circ\!\!\!-} = K_0{}^{\circ\!\!\!-} \cdot e^X \quad (14)$$

$K_0{}^{\circ\!\!\!-} = \exp[-\Delta_r G^{\circ\!\!\!-}/RT$ is the K-value at zero field, where $\Delta_r G^{\circ\!\!\!-}$ is the standard Gibbs reaction energy. At $F = 0$, $\Delta_r \hat{G}^{\circ\!\!\!-} = \Delta_r G^{\circ\!\!\!-}$. The "field effect exponent" X refers to the electric or magnetic free energy, respectively:

$$\Delta_r G_{(F)} = -\left(\Delta_r \hat{G}^{\circ\!\!\!-} - \Delta_r \hat{G}^{\circ\!\!\!-}\right) = RT \cdot \ln\left(\frac{K^{\circ\!\!\!-}}{K_0{}^{\circ\!\!\!-}}\right) \quad (15)$$

and

$$X = \frac{\Delta_r G_{(F)}}{RT} = \frac{\int \Delta_r M^{\circ\!\!\!-}\, dF}{RT} = \ln \frac{K^{\circ\!\!\!-}}{K_0{}^{\circ\!\!\!-}} \quad (16)$$

The integration boundaries are F and $F = 0$, respectively. If the apparent equilibrium constant K is not independent of the concentrations of the interaction partners or of the ionic strength, extrapolation to zero concentration or zero ionic strength yields the reaction-specific electrothermodynamic quantities $K^{\circ\!\!\!-}$, $K_0{}^{\circ\!\!\!-}$, and $\Delta_r M^{\circ\!\!\!-}$. Experimentally, it is usually K that is accessible via the fractional extent of a process. Substitution of Eq. (9) into Eq. (13) yields

$$\left(\frac{\partial \ln |K|}{\partial F}\right)_{p,T} = \frac{\Delta_r M^{\circ\!\!\!-}}{RT} - \frac{\partial \ln(Y_E/Y)}{\partial F} \quad (17)$$

The absolute signs refer to cases of K with a concentration dimension. Integration results in

$$K = K_0 \cdot e^X \cdot \frac{Y}{Y_E} \quad (18)$$

where Y is the normal activity factor at $F = 0$ and, purely formally, Y_E is that at F. If Y can be considered independent of F, the approximation of $Y/Y_E = 1$ holds and $K = K_0 \cdot e^X$ is used instead of Eq. (14).

In the case of induced dipole changes caused by the electric displaceability of ionic groups i, in an external field E, for instance, in a gating protein, $\Delta_r M = N_A \cdot \Delta_r \alpha \cdot E_{int}$ may be used. If the internal field E_{int} can be set equal

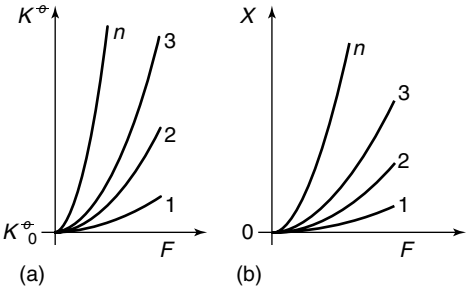

Fig. 2 Field dependences of (a) the equilibrium constant $K^{\ominus} = K_0^{\ominus} e^X$ and (b) the field-effect exponent $X = \int \Delta_r M dF/(RT) \propto F^2$. The steepness $(\partial K/\partial F)_{p,T} = K \cdot \Delta_r M/RT$ and $(\partial X/\partial F)_{p,T} = \Delta_r M/RT$ both increase with $\Delta_r M$ and with the domain size n. Since the relative change $\Delta\beta/\beta_0$ in the advancement of a chemical process is proportional to $X \propto F^2$, we obtain $\Delta\beta/\beta_0 \propto F^2$. The rate constants k exhibit qualitatively the same field dependences as K; therefore, generally $\Delta k/k_0$ is proportional to F^2.

to E, the molecular reaction polarization $\Delta_r\alpha = \alpha_p - \alpha_r$ reflects an average over the displacements of all groups i. Substitution into Eq. (16) yields (with $F = E$)

$$X = \frac{\int \Delta_r M \, dE}{RT} = \frac{\Delta_r\alpha \cdot E^2}{2k_B T} \qquad (19)$$

In the simplest case, a permanent dipole rotation in a planar membrane is indicated, if $X = \Delta_r M \cdot E/(RT)$ is linearly dependent on E. On the other hand, if X depends on E^2, Eq. (19) is used to determine the average reaction polarizability of an induced dipole mechanism.

3.2 The Weak-field Approximation

When $\Delta_r G_{(F)} \ll RT$, then $X \ll 1$ and the factor e^X in $K = K_0 e^X$ can be expanded into a power series $e^X = 1 + X + \ldots$, where higher order terms are negligibly small. Therefore, for small field effects, Eq. (14) takes the form $K^{\ominus} = K_0^{\ominus}(1 + X)$.

For practical purposes, a relative change $\Delta K/K_0$ is introduced, which readily permits expression of field-induced changes in percent. With $K = K_0 e^X$ as an approximation to $K^{\ominus} = K_0^{\ominus} e^X$, we obtain

$$\frac{\Delta K}{K_0} = \frac{K - K_0}{K_0} = e^X - 1 \qquad (20)$$

The small-field approximation ($X \ll 1$) now reads

$$\frac{\Delta K}{K_0} = X \qquad (21)$$

For small field effects in a random ensemble of permanent or induced dipolar reaction partners, $\langle \Delta_r m \rangle$ is proportional to F. Hence, X is proportional to $F^2/(2RT)$ and thereby $\Delta K/K_0$ is proportional to $F^2/(2RT)$; see Fig. 2. In summary, if $\Delta_r M \cdot F \ll RT$, the field-induced changes in the equilibrium concentrations are proportional to the *square* of the field strength.

The electromagnetodynamic approach so far gives general guidelines for the experimental access to field effects. On the other hand, the analysis clearly shows that it is not so much the magnitude of the individual moments of the reaction partners that matters; rather, the *moment difference* as the reaction moment must be nonzero for finite field effects.

We also see in $K = K_0(1 + X)$ and $X = \int \langle \Delta_r m \rangle dE/k_B T$ that, no matter how small the *difference* $\langle \Delta_r m \rangle$ in the electric or magnetic dipole moments of the

interaction partners is, there is *always a finite change* caused by a field. Of course, the inevitable thermal motion leads to local activity fluctuations $\delta a_j = \gamma_j \delta c_j + c_j \delta \gamma_j$. We must determine the *relevance* of the small, field-induced changes Δc_j and $\Delta \gamma_j$ in concentration and activity coefficient respectively compared with the random thermal fluctuations $\pm \delta c_j$ and $\pm \delta \gamma_j$.

3.3 Conformational State Transition

In a field, an intramolecular state transition or conformational change of the type.

$$B \rightleftharpoons B', \tag{22}$$

proceeds in the direction of B′, if the dipole moment $m(B') > m(B)$, and hence the following equation holds:

$$\langle \Delta_r m \rangle = \mathbf{m}(B')\langle \cos\theta \rangle - \mathbf{m}(B)\langle \cos\theta \rangle > 0.$$

When the degree of transition is defined as $\beta = [B']/[B_T]$, where $[B_T]$ is the concentration of all binding sites (or all states $[B_T] = [B] + [B']$), we obtain:

$$K = \frac{[B']}{[B]} = \frac{\beta}{1-\beta} = K_0 \cdot e^X \tag{23}$$

$$\beta = \frac{K_0 e^X}{1 + K_0 e^X} \tag{24}$$

The weak-field approximation ($X \ll 1$, $e^X = 1 + X$) yields $\Delta K / K_0 = X$ and

$$\frac{\Delta\beta}{\beta_0} = \frac{\beta - \beta_0}{\beta_0} = X \cdot \frac{1}{1 + K_0} \tag{25}$$

Thus, the relative shifts in both K and in β are linearly dependent on X. If $K_0 \ll 1$, we obtain $\Delta\beta/\beta_0 = X$. Here too, the F-dependence of X yields $\Delta_r M$ or $\Delta_r \alpha$.

3.4 Ligand Binding

For the analysis, the ligand-binding equilibrium is written in the direction of dissociation

$$LB \rightleftharpoons L + B \tag{26}$$

The degree of ligand association is defined by

$$\beta = \frac{[LB]}{[B_T]} = \frac{[L]}{[L] + K} \tag{27}$$

where K is given by the total concentrations $[L_T]$ and $[B_T]$ of ligand and binding site, respectively:

$$K = \frac{[L][B]}{[LB]} = ([L_T] - \beta[B_T]) \cdot \frac{1-\beta}{\beta} \tag{28}$$

Using $(1-a)^{1/2} \approx 1 - \frac{1}{2}a$ if $a < 1$, we obtain

$$\beta \approx \frac{[L_T]}{[L_T] + [B_T] + K} \tag{29}$$

The field-induced relative change $\Delta\beta/\beta_0$ then is

$$\frac{\Delta\beta}{\beta_0} \approx \frac{K_0 \left(1 - e^X\right)}{[L_T] + [B_T] + K_0 e^X} \tag{30}$$

The weak-field approximation ($X \ll 1$) yields

$$\frac{\Delta\beta}{\beta_0} \approx -X \cdot \left[1 + \frac{([L_T] + [B_T])}{K_0}\right]^{-1} \tag{31}$$

Here too, the relative change in β is proportional to X. Note that for Eq. (26), we have $\langle \Delta_r m \rangle = (\langle m_L \rangle + \langle m_B \rangle) - \langle m_{LB} \rangle$.

3.5 Dipole-pairing

Frequently, the pair association of dipolar species (B) is found to involve major dipole moment changes $\langle \Delta_r m \rangle$ if the pairing

reduces the dipole moment to zero by antiparallel alignment. Therefore, $\langle \Delta_r m \rangle$ for a dimerization reaction of the type

$$BB \rightleftharpoons 2B \tag{32}$$

is given by $\langle \Delta_r m \rangle = 2\langle mB \rangle - \langle m\ BB \rangle = 2\langle mB \rangle$. For this case, we have

$$\beta = \frac{2[B \cdot B]}{[B_T]} = \frac{[B]}{[B] + K/2} \tag{33}$$

$$K = \frac{[B]^2}{[BB]} = \frac{(1-\beta)^2}{\beta}[B_T] \tag{34}$$

Hence,

$$\beta \approx \frac{[B_T]}{[B]_T + K/2}. \tag{35}$$

The weak-field approximation reads as follows:

$$\frac{\Delta\beta}{\beta_0} \approx -X\left(1 + 2\frac{[B_T]}{K_0}\right)^{-1} \tag{36}$$

describing the decrease in the pair complex with increasing field strength.

4 Rate Constants

When time courses of field-induced processes can be resolved, the time constants or experimental rate coefficients can be analyzed in terms of individual rate constants. Generally, when equilibrium constants are field-dependent, the two rate constants must depend differently on the field strength.

4.1 Dipole Transitions

The equilibrium constant for the general Eq. (10) is given by

$$K = \frac{\Pi_p c_p{}^{\nu_p}}{\Pi_r c_r{}^{|\nu_r|}} = \frac{k_r}{k_p} \quad \text{and} \quad K^{\ddagger} = \frac{k_r{}^{\ddagger}}{k_p{}^{\ddagger}} \tag{37}$$

The reaction moment $\Delta_r m$ may be related to the kinetic activation moments M_a by

$$\Delta_r M^{\ddagger} = M_{a,r} - M_{a,p} \tag{38}$$

Similarly, the field effect exponents are connected by

$$X = X_{a,r} - X_{a,p}^{-} \tag{39}$$

Analogous to $K^{\ddagger} = K_0{}^{\ddagger}\, e^X$, we obtain

$$k^{\ddagger} = k_0{}^{\ddagger} \cdot e^{X_a} \tag{40}$$

where the field effect factor is defined by

$$x_a = \frac{G_a}{RT} = \frac{\int M_a\, dF}{RT} = \ln\left(\frac{k^{\ddagger}}{k_0{}^{\ddagger}}\right) \tag{41}$$

The weak-field approximation ($x_a \ll 1$) yields $k^{\ddagger} = k_0{}^{\ddagger}(1 + x_a)$.

The field-induced relative change of k' is generally given by

$$\frac{\Delta k^{\ddagger}}{k_0{}^{\ddagger}} = e^{X_a} - 1 \tag{42}$$

Hence, the weak-field approximation reads

$$\frac{\Delta k^{\ddagger}}{k_0{}^{\ddagger}} = x_a \tag{43}$$

Like the field-induced small shifts in K and β, the relative change in the rate coefficients of dipolar equilibria are linearly dependent on x_a; frequently x_a is proportional to F^2.

If the experimental rate coefficient k is analyzed in terms of the Eyring transition state theory, we have $k = k^{\neq} K^{\neq} \kappa$, where κ is an adjustable parameter and $k^{\neq} = k_B T/h$ is a universal decay constant and $K^{\neq}$ and $\Delta_r M^{\neq}$ are the equilibrium constant and the reaction moment respectively of the assumed rapid preequilibrium. For this case, M_a associated with k is given by $M_a = \Delta_r M^{\neq}$. Since the Eyring approach is not applicable in condensed

matter, any such approach is purely formalistic.

On the other hand, we may equally well assume that the activation moments M_a are determined by the actual dipole moments (**m**) of the educts and products. Hence,

$$M_{a,p} = N_A \cdot \Sigma_p \nu_p |\mathbf{m}_p| \langle \cos\theta \rangle$$
$$M_{a,r} = N_A \cdot \Sigma_r |\nu_r \| \mathbf{m}_r| \langle \cos\theta \rangle \quad (44)$$

Nonidealities are covered by the activity coefficients. With $K^{\ominus} = k_r{}^{\ominus}/k_p{}^{\ominus}$, we formally have

$$k_r = k_r{}^{\ominus} \cdot Y_r, \text{ and } k_p = k_p{}^{\ominus} \cdot Y_p \quad (45)$$

The field-effect exponent of Eq. (41) is specified analogous to Eq. (18) as

$$x_a = \ln\left(\frac{k^{\ominus}}{k_0{}^{\ominus}}\right) = \ln\left(\frac{k}{k_0}\right) + \ln\left(\frac{Y_E}{Y}\right) \quad (46)$$

where Y refers to the respective activity coefficient term at E and in the absence of E, respectively.

If, by chemical relaxation spectrometry, the rate coefficients can be determined separately, the *activation dipole moments* of the interacting reaction partners can be estimated from the field dependence of the k values.

4.2 Ion Equilibrium

According to Onsager, it is only the dissociation rate constant k_{dis} of the separation of an ion pair that is primarily affected by an electric field **E**:

$$L^{z+} \cdot B^{z-} \underset{k_{ass}}{\overset{k_{dis}}{\rightleftharpoons}} L^{z+} + B^{z-} \quad (47)$$

In the linear range, Onsager's theory of very diluted weak electrolytes (z_+/z_-) yields

$$\left(\frac{\partial \ln\left|k_{dis}^{\ominus}\right|}{\partial |\mathbf{E}_0|}\right)_{p,T} = \frac{(z_L u_L - z_B u_B)|z_L \cdot z_B| e_0^3}{(u_L + u_B) 8\pi\varepsilon_0 \varepsilon (k_B T)^2} = \gamma \quad (48)$$

where u_L and u_B are the electric mobilities of the separated ionic species; see Eq. (1). For symmetric electrolytes where $z_L = -z_B = |z|$, Eq. (48) is reduced to $\gamma = |z^3|\, e_0^3/[8\pi\varepsilon_0\varepsilon(k_B T)^2]$.

If the actual dipole moment of the ion pair L · B is not zero (such as the electric dipole moments of the $MgSO_4$ ion pairs) and if the reaction occurs at higher salt concentrations, we use the expressions

$$k_{dis} = k_{dis}^{\ominus} \cdot Y_d \quad \text{and} \quad k_{ass} = k_{ass}^{\ominus} Y_a \quad (49)$$

Integration of Eq. (48) yields

$$X_{a,r} = \ln\left(\frac{k_{dis}^{\ominus}}{k_{d,0}^{\ominus}}\right) = \gamma \cdot |\mathbf{E}_0| \quad (50)$$

and

$$\ln\left(\frac{k_{dis}}{k_{d,0}}\right) = \gamma |\mathbf{E}_0| - \ln\left(\frac{Y_d{}^{(E)}}{Y_d}\right) \quad (51)$$

When the dipole moment of the ion pair L · B in the simple reaction $LB = L^+ + B^-$ is dependent on the ionic strength because of screening by ionic "half clouds", we may analyse the k_a data according to, $\ln|k_{ass}| = \ln\left|k_{a,0}\right| + X_{a,p} - \ln(Y_a(F)/Y_a)$ with $Y_a(F) = Y_a$ at F. Applying

$$\frac{d \ln|k_{ass}|}{dF} = \frac{M_{a,p}}{RT}, \quad (52)$$

$M_{a,p}$ can be determined. Consistency may be checked using Eq. (38), connecting the field dependencies of K, k_r, and k_p, respectively.

Often, it is useful to define a degree of dissociation by $\alpha = [B]/[B_T]$. If the reaction is symmetric ($[L_T] = [B_T]$), we have:

$$K = \frac{\alpha^2}{1-\alpha}[B_T] \tag{53}$$

The small-field approximation of the relative change in the degree of dissociation is derived analogous to Eq. (31), resulting in:

$$\frac{\Delta\alpha}{\alpha_0} \approx x\left(3 + \frac{K_0}{[B_T]} + \frac{2[B_T]}{K_0}\right)^{-1} \tag{54}$$

Formally, the field dependence of K can be calculated from that of k_{dis} and k_{ass} and formally described as $\Delta K/K_0 = x_{a,r} - x_{a,p}$. See Eqs. (21 and 43).

4.3 Activity Coefficients

Thermodynamic activity coefficients and the theoretical approaches are defined for equilibrium conditions only. The **E** and **B** field effects on electrolytes, however, represent nonequilibrium situations. Under stationary conditions, we may consider the field-induced distortion of screening ionic atmospheres and other local changes in the ion concentration as actual steady state changes αc_i. Purely formally, we introduce the relative change $\Delta\gamma_i/\gamma_i$ in the (theoretically individual) activity coefficient γ_i of the ion (or ionic group) of type i.

The Debye–Hückel approximation for a moderately diluted solution is purely formally given by

$$\ln\gamma_i = \frac{-z_i^2 A' \cdot I_c^{1/2}}{\left(1 + B' I_c^{1/2}\right)} \tag{55}$$

where A' is a (temperature-dependent) constant, B' a parameter containing the encounter distance and

$$I_c = 0.5 \sum_i z_i^2 c_i \tag{56}$$

is the ionic strength (including all ions i).

For elementary reactions between ionic partners like those in Eq. (47), we have in general

$$\ln Y = \frac{2 z_+ z_- A' \cdot I_c^{1/2}}{\left(1 + B' I_c^{1/2}\right)} \tag{57}$$

The small-field approximation is specified as

$$\ln\left(\frac{Y_E}{Y}\right) = \ln\left(1 + \frac{\Delta Y}{Y}\right) = \frac{\Delta Y}{Y} \tag{58}$$

Because $\ln Y$ is proportional to $I_c^{1/2}$, we obtain for $\Delta I_c = I_c$,

$$\ln\left(\frac{Y_E}{Y}\right) = \left(1 + \frac{\Delta I_c}{I_c}\right)^{1/2} \approx 1 + \frac{\Delta I_c}{2 I_c} \tag{59}$$

where $\Delta I_c = \sum_i z_i^2 \Delta c_i/2$ covers the field-induced local changes in the screening ions, which may be measured as a Wien effect (conductivity increase due to F).

Similarly, field effects on rate coefficients may also involve changes in the respective Y coefficients. The concentration changes Δc_i entering into ΔI_c and thus into the relative changes of K, α, and k may also contain contributions from the ionic currents induced by the fields.

4.4 Ion Flows

The electrodiffusive flows of the cellular ions Na^+, K^+, Ca^{2+}, and Cl^- through electrochemically gated channels of membranes are dependent on the local ion concentrations c_i and on induced local field changes.

The flow density vector $\mathbf{i}_i$ (mol/sm^2) of the ion type *i* is given by the Nernst–Planck equation for the flow direction **r**

$$|\mathbf{i}_i| = -D_i \left(\frac{\partial c_i}{\partial r} + \frac{z_i c_i F}{RT} \frac{\partial \varphi}{\partial r} \right) \qquad (60)$$

where D_i is the diffusion coefficient, $F = e_0 N_A$ is the Faraday constant, and $\partial\varphi/\partial r = -E$ is the electric potential gradient at site **r**.

The current density vector is then

$$\mathbf{J} = F \sum_i z_i i_i = \kappa \cdot \mathbf{E} \qquad (61)$$

The relative changes $\Delta J/J_0$ are caused by a change in **E** or in the ion concentrations, or in both. Finally, the change in the transmembrane voltage (or membrane field E_m) may directly change the conformation of a membrane transport–gating protein or of a membrane-associated enzyme.

5 Amplification Mechanisms

Natural electric and magnetic field reception operates at small external field strengths. The molecular reaction moments of the interacting, directly "field-receiving" charges and electric and magnetic dipoles are relatively small ($\Delta_r G_{(F)}/RT \ll 1$). Obviously, there must be amplification mechanisms for both, enhancement of the field (resulting in larger internal fields and ion flows) on the one hand and enhancement of local chemical reactivities on the other hand.

If a chemical amplification cascade enhances a substrate signal from the level $[S_0]$ to the product level $[P_0]$, a relevant external field effect must already change the substrate concentration by a significant amount $\Delta[S]$. The cascade that may contain a network of nonlinear couplings of reaction and diffusion flows will process the relative change $\Delta[S]/[S_0]$ to the output $\Delta[P]/[P_0] = \Delta[S]/[S_0]$. Hence, the relative amplification will not change unless there are significant field effects on the local elements of the cascade itself.

The distribution of electric organs in rows of larger skin areas of electric fish or the strings of magnetosomes in magnetobacteria and other species suggest that geometrical factors are essential in adding up signals from many inputs. The feedback system of many innervated sensor and emitter organs even enables the organisms to differentiate between inanimate ohmic-dissipative matter and capacitively storing biomatter of cells (organelles and lipid/protein membranes). Besides the special structure, form, and shapes of the sensory receptors, there are some general principles for molecular enhancement and amplification processes.

5.1 Field Enhancement

At interfaces of matter with different relative permittivity (dielectric constant ε) such as plasma membranes, applied fields cause ion accumulations, which ionically charge up cells, organelles, and larger macromolecules (like condensers).

If a macromolecule is considered as a spherical microdroplet continuum ε_2 in aqueous solution ($\varepsilon_1 = 80$ at 20 °C), the induced field across the center is given by:

$$\mathbf{E}_{ind} = \frac{3\varepsilon_1}{2\varepsilon_1 + \varepsilon_2} \mathbf{E}_0 \qquad (62)$$

Since usually $\varepsilon_2 < \varepsilon_1$, we obtain $\mathbf{E}_{ind} \leq 1.5\ \mathbf{E}_0$. Note that Eq. (62) is applicable if the conductivity term in the complex dielectric permittivity is negligible.

A much larger field amplification occurs when single cells or organelles

or even clusters of cells and tissue pieces are exposed to external fields ($\mathbf{E}_0$). The ionic interfacial polarization causes induced electric potential differences $\Delta\varphi_{\text{ind}}$ that, in the time range of microseconds to milliseconds, because of the conducting cell interior, occur only across the plasma membranes (see Fig. 3a). For spherical cells, the induced transmembrane potential difference in the direction x of the external field $\mathbf{E}_0$, in the stationary state of ionic interfacial polarization – polarization time $\tau_{\text{pol}} \ll \text{t}$, such that $\Delta\varphi(\text{t}) = \Delta\varphi\left(1 - \text{e}^{-\text{t}/\tau}\right)$ – is given by $\Delta\varphi_{\text{ind}} = -1.5\ \text{f}(\lambda)(\mathbf{E} \cdot \mathbf{a})$. Hence,

$$\Delta\varphi_{\text{ind}}(\theta) = -\frac{3}{2}\,\text{a f}\,(\lambda)|\mathbf{E}_0||\cos\theta| \quad (63)$$

where θ is the angle between the membrane position of the tip of the radius vector **a** and the positive x-axis ($\mathbf{E}_0$) through the sphere midpoint (Fig. 3). The conductivity factor $\text{f}(\lambda) \leq 1$ depends on the ratio a/d_{m} and on the conductivities λ_{m}, λ_{in}, and λ_{ex}

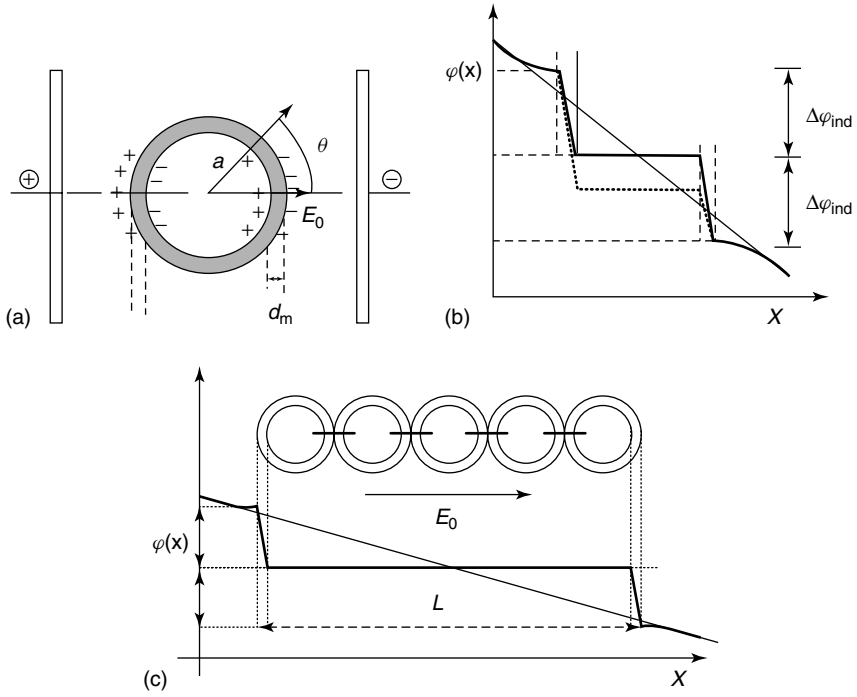

Fig. 3 Field amplification by interfacial polarization through DC and low-frequency **E** fields. (a) Single-cell sphere of the radius vector **a**, and the membrane thickness d_{m}. The angle θ defines the membrane position of the tip of the radius vector **a** relative to the direction of $\mathbf{E}_0$ (x-direction). The dashed fat line refers to $\Delta\varphi_{\text{m}} = \Delta\varphi_{\text{ind}} + \Delta\varphi_{\text{nat}}$ (at $\theta = 180^\circ$, $\theta = 0^\circ$), where in this example, the resting membrane potential $\Delta\varphi_{\text{nat}} < 0$ and also $\Delta\varphi_{\text{ind}} < 0$ (Eq. 64). (b) Electric potential profile $\varphi(\text{x})$ in the direction x of the external field vector $\mathbf{E}_0$ through the pole caps and the midpoint of the sphere. The steep potential drop across the membranes (in the direction of $\mathbf{E}_0$) is given by $\Delta\varphi_{\text{ind}}(\theta) = -1.5\ E_0 \text{a} \cdot |\cos\theta|$, if the conductivity of the membrane is very small compared to that of the cell inside and outside and $a/d_{\text{m}} \gg 1$. The field amplification factor at the pole caps is $\text{f}(a) = (E_{\text{ind}}/E_0) = 1.5a/d_{\text{m}}$. (c) Array of cells connected by conducting gap junctions. The field amplification factor is $\text{f}(L) = (E_{\text{ind}}/E_0) = 1.5L/d_{\text{m}}$.

of the membrane, the cell interior, and the outside medium respectively.

If $a/d_m \gg 1$, $\lambda_m \ll \lambda_{ex}$, λ_{in} holds and the f(λ) factor is given by $f(\lambda) = 1 - \lambda_m(a/d_m)(\lambda_{ex} + \lambda_{in}/2/(\lambda_{in} \cdot \lambda_{ex})$. At the pole caps, that is, at $\theta = 0^\circ$ (right side) and $\theta = 180^\circ$ (left side in $\mathbf{E}_0$ direction, Fig. 3) hence $\cos\theta = \pm 1$, the induced transmembrane voltage is maximum, and correspondingly

$$|\mathbf{E}_{ind}| = -\frac{\Delta\varphi_{ind}}{d_m} = \frac{3}{2}\frac{a}{d_m}|\mathbf{E}_0| \qquad (64)$$

The amplification factor is defined by

$$f(a) = \frac{|E_{ind}|}{|E_0|} = \frac{3a}{2d} \qquad (65)$$

For a cell radius of $a = 10\,\mu m$ and the membrane thickness $d_m = 5$ nm, $f(a) = 3 \times 10^3$. Hence, interfacial polarization can very appreciably amplify weak external fields; this type of amplification mechanism is the basis for all the electroporation phenomena.

Interfacial polarization not only amplifies external fields. In addition, the induced potential difference is superposed on the natural potential difference of cell membranes, $\Delta\varphi_m \approx -100$ mV, where the electric potential of the outside is arbitrarily taken to be zero. Note that $\Delta\varphi_{nat}$ is independent of θ. The actual transmembrane potential in the direction of $\mathbf{E}_0$ is given by

$$\Delta\varphi = -\left[\frac{3}{2}af(\lambda)|\mathbf{E}_0| + \frac{\Delta\varphi_m}{\cos\theta}\right]|\cos\theta| \qquad (66)$$

Since $E_m(\theta) = -\Delta\varphi_m(\theta)/d_m = E_{ind}(\theta) + E_{nat}$, where $E_{nat} = -\Delta\varphi_{nat}|\cos\theta|/(d_m \cos\theta)$, it is seen that at the left pole cap, $\cos\theta = -1 E_m > E_{ind}$ and at the right pole cap, $(\cos\theta = 1) E_m < E_{ind}$. If $\Delta\varphi_{nat} < 0$, the left cap is hyperpolarized and the right cap is depolarized, and the membrane proteins and transport processes in the two pole caps are differently affected by $\mathbf{E}_0$. Therefore, a longer-lasting DC field may produce appreciably large asymmetric field effects.

At the pole caps of oriented bacteria of length L, the induced transmembrane potential difference is

$$\Delta\varphi_{ind} = -0.5L|\mathbf{E}_0| \qquad (67)$$

and the amplification factor is $f(L) = L/2d_m$. Here too, the field effect is asymmetric at the two pole caps.

Another important example of field amplification by geometrical factors consists of a series of cells connected by gap junctions. Such a string of cells in series resembles a single elongated cell. In an applied external field, the outer pole cap of the head cell and that of the tail cell experience the induced potential drop $\Delta\varphi_{ind} = -0.5L|\mathbf{E}_0|$, where L is the length of the string (Fig. 3b). The amplification factor f(L) increases with L and may become very large. Here too, the field effect is asymmetric with respect to the natural membrane voltage in the head and the tail cell.

5.2 Cooperativity and Phase Transition

In systems with domain structures, the molecules of a domain are cooperatively coupled. A domain changing state or, more specifically, molecular orientations as a whole, is described by

$$B_n \rightleftharpoons B'_n \qquad (68)$$

where n is the number of cooperatively coupled molecules (domain size) and B′ represents the (orientational) state favored in the presence of an applied field because of higher moment.

In the simplest case, the collective transition of a domain is described by the

field-effect exponent

$$X_n = \frac{\Delta_r G_{n(F)}}{RT} = \frac{\int \Delta_r M_n \mathrm{d}F}{RT} \qquad (69)$$

where $X_n = nX$ and $\Delta_r M_n = n\Delta_r M$.

For an ensemble of independent domains of different sizes, we may formalize a distribution constant

$$K(\bar{n})^{\bar{n}} = K_0{}^{\bar{n}} \cdot \exp(X_n) \qquad (70)$$

where $\bar{n}$ is the mean domain size, representing a kind of cooperative amplification factor for the reaction moment $\Delta_r M$.

If $\bar{n} \gg 1$, very steep phase transitions can occur in a very narrow field strength range. Thus, even a weak external field may have a large effect (see Fig. 2).

If a reaction domain with the polarization volume V_n can be specified, the orientational rearrangement within a domain may be subjected to a continuum approach where the polarization P has different values in the two states and B'_n. If $\Delta_r P = P(B'_n) - P(B_n) = N_A \Delta_r p$ is the reaction polarization, straightforward electrodynamics yields

$$\Delta_r M_n = V_n \cdot \Delta_r p \cdot N_A. \qquad (71)$$

Specifically, the electric and magnetic polarization differences are given by

$$\Delta P_{el} = \varepsilon_0 \Delta\chi_{el} |\mathbf{E}| = \varepsilon_0 \cdot \Delta\varepsilon |\mathbf{E}|$$
$$\Delta P_{ma} = \mu_0^{-1} \Delta\chi_{ma} |\mathbf{B}| \qquad (72)$$

where the $\Delta\chi_{el}$ and $\Delta\chi_{ma}$ are the susceptibility differences, respectively. If the domain refers to the formation of an aqueous pore in a lipid bilayer membrane, $\Delta\chi_{el} = \Delta\varepsilon = \varepsilon_m - \varepsilon_w$ is used (because $\chi_{el} = \varepsilon - 1$), where $\varepsilon_m = \varepsilon(\text{lipid}) \approx 2$ and $\varepsilon_w \approx 80$ are the dielectric constants of the membrane and the pore water respectively.

The field-effect exponents at constant domain volume are derived from Eq. (71):

$$\chi_{el} = \frac{\varepsilon_0 V_n \cdot \Delta\chi_{el}}{2k_B T} g |\mathbf{E}_0|^2 \qquad (73)$$

where g is a shape factor [2] and

$$x_{ma} = \frac{V_n \cdot \Delta\chi_{ma}}{2\mu_0 k_B T} |\mathbf{B}|^2 \qquad (74)$$

In an ensemble of domains, V_n represents the size average $V_{\bar{n}}$.

More specifically, a domain orientation function ϕ^{OR} may be used, which is different for permanent ($\mathbf{m}_p$) and induced ($\mathbf{m}_{ind}$) dipole mechanisms [5]. For uniaxial permanent dipoles, we have

$$\phi^{OR}_{perm} = 1 - \frac{3}{x_p}\left(\coth x_p - \frac{1}{x_p}\right) \qquad (75)$$

where $x = |\mathbf{m}_p| F_{dir}/(k_B T)$. For $F = E$, E_{dir} is the Onsager directing field [3]. If $x_p = 1$, the weak-field approximation yields $\phi^{OR}_p = x_p^2/15$ as the first term of a power series.

The orientation function for induced electric dipoles $\mathbf{m}_{ind} = \alpha \cdot \mathbf{E}_{int}$, where α is the polarizability tensor and $\mathbf{E}_{int}$ is the internal field, is given by

$$\phi^{OR}_{ind} = \frac{3}{4}\left(\frac{e^{x_{ind}}}{x_{ind}^{1/2}\int dy\, e^{y^2}}\right) - \frac{1}{2} \qquad (76)$$

where $x_{ind} = \alpha \cdot g_i |\mathbf{E}_0|^2/(2k_B T)$, and $g_i = |\mathbf{E}_{int}|/|\mathbf{E}_0|$ is the shape factor.

If $x_{ind} \ll 1$, the weak-field expression yields

$$\phi^{OR}_{ind} = \frac{2x_{ind}}{15} \propto |\mathbf{E}_0|^2.$$

orientation function are experimentally accessible by electrooptical relaxation techniques.

In the case of domain systems, we have

$$x_p(n) = \frac{n|\mathbf{m}_p|F_{dir}}{k_B T} \qquad (77)$$

and

$$x_{ind}(n) = \frac{n \cdot \alpha \cdot g_i|\mathbf{E}_0|^2}{2k_B T}. \qquad (78)$$

If $n \gg 1$, the amplification of small molecular field effects may be appreciably large (see Fig. 2).

5.3 Amplification at High Basis Fields

A particular amplification mode resides directly in the field dependence of equilibrium constants K. This enhancement mode appears to be especially important for all membrane processes occurring in the strong natural transmembrane fields.

From Eqs. (13 and 17), it is seen that the steepness of the $K(X)$ relationship, given by

$$\left(\frac{\partial K}{\partial F}\right)_{p,T} = \frac{K(E)\Delta_r M^{\ddagger}}{RT}, \qquad (79)$$

depends not only on $\Delta_r M^{\ddagger}$ but also on $K(E)$ itself.

If an external field causes an induced field $|\mathbf{E}_{ind}| = \Delta E_0$ at the level E_{nat} of the resting membrane potential difference ($\Delta\varphi_{nat} = -E_{nat}d_m$), the relative change $\Delta K/K(E_{nat})$ is larger than $\Delta K'/K_0$ at $E_{nat} = 0$ for the same ΔE_0 value (Fig. 4). The inequality $\Delta K/K(E_{nat}) > \Delta K'/K_0$ is due to the field dependence of the reaction moment $\Delta_r M(\propto F)$. Therefore, in terms of the field-effect exponents, we have for the different integration boundaries

$$X(E_{nat} \longrightarrow E_{nat} + \Delta E_0) > X(E_{nat} \longrightarrow E_{nat} - \Delta E_0).$$

If the external force is an oscillatory (AC) field, say, $\mathbf{E}_0(f) = \hat{\mathbf{E}}_0 \sin(2\pi ft)$ where $\hat{\mathbf{E}}_0$ is the peak amplitude, the enforced oscillatory change in the equilibrium constant of a reaction is asymmetric: $\Delta K_+/K(E_{nat}) \neq \Delta K_-/K(E_{nat})$; see Fig. 4. For instance, the induced concentration changes Δc_+ are larger for one AC field direction ($+\Delta E_0$) compared to the Δc_- values of the other direction ($-\Delta E_0$). In a similar way, the change in the forward rate constant is different from that of the reverse rate constant.

5.4 Comparison of AC/DC Effects

In DC fields, freely mobile charges and dipoles are translationally or rotationally net-displaced. In AC fields, however, the motions are oscillatory around a mean position. If the frequency of the AC field is too high, inertia and viscosity may prevent the species from following the variation of the external fields. On the other hand, fields acting on an ensemble of charges and dipoles may enforce and synchronize the individually random motions into a *concerted collective motion* of all the interaction partners. Such an externally enforced cooperation may bias in one direction an otherwise random fluctuation and produce the small net concentration changes involved in weak-field reception.

The interpretation of the experimental data on weak-field effects is still very controversial. The formalism outlined here may help in two ways: (1) in the design of experiments that use both species and sample size as variables, and (2) in the analysis of data in terms of thermodynamic and kinetic parameters consistent with the first principles of chemical reactivity in electric and magnetic fields.

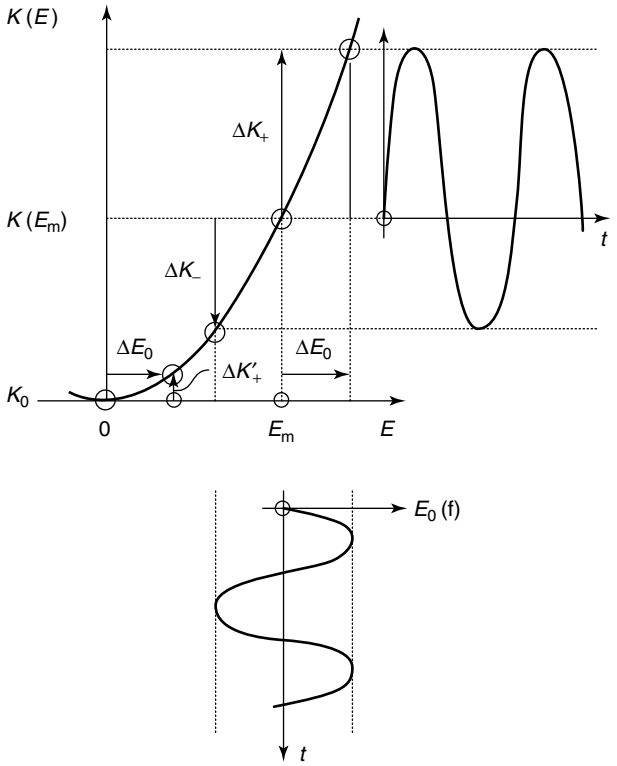

Fig. 4 Amplification at high field and asymmetric field effect for oscillatory external fields (AC). Application of an external field, inducing $E_{ind} = \Delta|\mathbf{E}_0|$, at $E = 0$, causes only a small change $\Delta K'_+$. If applied at $E = E_{nat}$ (e.g. at the resting potential $\Delta\varphi_{nat} \approx 0.1$V), the same external field causes a much larger change ΔK_+, because $\Delta K/\Delta E = K(E)\Delta_r M/(RT)$ depends on $K(E)$. The asymmetry of the $K(E)$ dependence leads to an asymmetric amplification of K: $\Delta K_+ > \Delta K_-$, if the symmetric external field $\mathbf{E}_{0(f)} = \hat{\mathbf{E}}_0 \cdot \sin\cdot(2\pi f \cdot t)$ operates at E_{nat}. At $E = 0$, $\Delta K_+ = \Delta K_-$. In a similar way, the rate constant k is asymmetrically dependent on $\mathbf{E}_0(f)$.

There is continued public concern on possible health risks of weak electromagnetic fields, that is, of field intensities that are very small compared to those of the natural geofields.

As indicated here, the problem is not that there are always finite effects that in principle, may either be benefical or bear a risk. The still unresolved question is *whether and how*, if at all, the small and insignificant local changes in the concentrations of the biochemical reaction partners may be amplified such that they emerge out of the natural thermal fluctuations. Despite the various experimental and theoretical activities aiming at knowledge to identify and to understand such mechanisms, no general conclusive and convincing answers can yet be given for the various claims of finite small field-effects.

Keywords

Transmission Electron Microscopy (TEM)
Electrons passing through the specimen form the image. Transmission of electrons through the specimen depends on the accelerating voltage, routinely 80 to 120 KV for specimens thinner than 300 nm, but for thicker specimens, or for higher resolution voltages up to 1000 K can be used.

EM grid
A 3-mm diameter, 0.01-mm (10–15 μm) thick disc of metal (usually copper) with regular perforations. The specimen is placed on the grid and those parts of the specimen that lie across the perforations are visualized in the EM.

Scanning Electron Microscopy (SEM)
This approach is used to visualize the specimen surface. An electron probe scans the surface and the secondary electrons are recorded in relation to the moving point of the probe.

Specimen Preparation
The foundation of all EM. These are highly empirical methods that have been developed for all EM approaches, which allow the specimens to be imaged successfully. For TEM, the specimen must either be particulate, generally thinner than 500 nm, or it must be sectioned to that thickness, or thinner, after embedding in plastic, or after cryoimmobilization.

Vitrification
The process whereby liquid water is cooled so rapidly that the water molecules solidify without crystallization to form amorphous or vitreous ice. A vitrified specimen is considered to be cryoimmobilized.

Freeze Substitution
Vitrified specimens are infiltrated at low temperatures with solvents, usually with heavy metal stains such as osmium tetroxide or uranyl acetate. Following this low temperature stabilization, the specimen is infiltrated with resin at low temperature followed by ultraviolet light polymerization below −20 °C, or the specimen temperature is raised to room temperature prior to room temperature resin embedding.

Freeze-Fracture/Replica
A vitrified specimen is planarly split and coated with a thin layer of metal (such as platinum, tungsten, or tantalum). The biological material is digested away and the replica is placed on an EM grid or viewed in the frozen- hydrated state in a SEM. A useful modification, freeze-etching, involves subliming a surface layer of water molecules to reveal details of some internal structures before shadowing. For particles and macromolecular complexes, metal shadowing can be used to form a replica without the freezing step. Glycerol spraying is a related technique where the sample is sprayed into a glycerol suspension and then rotary-shadowed and viewed by TEM.

Immunogold Labeling
Visualization of antigens on sections, or on the surface of isolated particles using (primary) antibodies. These are detected generally using an additional reaction containing gold particles that have bound (secondary) antibodies, or protein-A, that recognize the primary antibodies.

Tomography
The procedure for collecting multiple tilt images of a set of particles, or structures in (mostly) thick sections or isolated particles and collating the information computationally to provide a three-dimensional model of the structure.

Image Analysis
Computing methods used to improve the signal-to-noise ratio of EM images. They are based on averaging the information from two-dimensional data sets and can reveal the three-dimensional structure.

Stereology
A set of sampling tools and geometrical probability–based principles that allow one to estimate relative and absolute three-dimensional structural quantities (such as volume, surface, length and number), and spatial relationships, from sectional images.

Most of the organelles discovered after 1945 were first seen by electron microscopy (EM) in thin sections of resin-embedded cells. Since that time, the technical advances in EM instrumentation and specimen preparation have been enormous, a consequence of physicists, engineers, and biologists working together. These methods now allow cell biologists to visualize unperturbed cell structures over a range of dimensions, from the atomic resolution in the case of single proteins or macromolecular complexes to the range from 2 nm and up in the case of cellular organelles. This level of resolution is far beyond what can be seen by light microscopy. This review will cover the essentials of a range of methods for scientists investigating cell biology using EM. The major emphasis will be on resolution levels poorer than 1 to 3 nm. In all these methods, the most crucial parameter is specimen preparation and, without doubt, the ''gold- standard'' reference technique, which involves vitrification by rapid freezing, in conjunction with cryo-EM.

1 Introduction

1.1 Why Do We Need EM in Cell Biology?

The main goal of this chapter is to convince the reader, especially cell biologists, that electron microscopy (EM) offers them an incredibly powerful set of approaches for analyzing the ultrastructure of cells and their components. Moreover, these methods have been developed to cover a vast scale of detail, ranging from the atomic level to the level of whole organisms. While high-resolution cryo-EM is thriving, the use of lower resolution EM has dropped considerably in recent times in cutting-edge cell biology research. There is no doubt that this downward trend is a direct effect of the availability of increasingly sophisticated state-of-the-art light microscopy (LM) approaches

that can, for example, detect individual fluorescent molecules under ideal conditions. Recently, even the long-considered lower limit to LM resolution (0.2 μm) has been reduced for detecting fluorescent molecules to below 0.1 μm. Such developments, while clearly very important, may even deceive more cell biologists into thinking that LM approaches can now do everything that was earlier considered in the realm of EM.

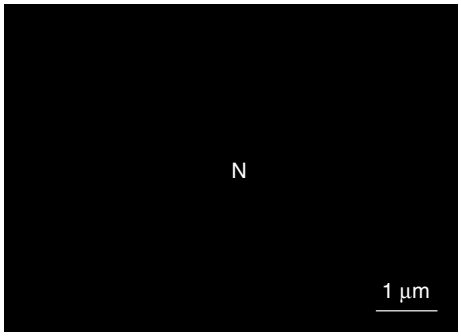
There is, however, a fundamental flaw to this argument. Even if one can see a single fluorescently labeled molecule in the cell, there is still the fundamental limitation with LM in *relating that signal to the defined structures in the cell*. An EM-thin section can reveal enormous detail of defined structures, such as membranes, filaments, or ribosomes; when this section is labeled with immunogold, the gold particles can be assigned to defined structures with high precision (within 8 to 20 nm). However, at the LM level, the fluorescence signal is mostly seen only as a nondescript blob. Often, one compares the immunolabeled signal from one protein in one color with respect to a compartment reference marker seen in a separate color. However, for such a reference marker to be useful, one needs to have shown first by EM that it is indeed restricted to the structure of interest. Figure 1(a) shows an example of immunofluorescence labeling of the Golgi complex, while Fig. 1(b) reveals how much more information becomes available when the same specimen is visualized at the EM level. Both methods provide important information, but at different, complementary scales.

State-of-the-art LM is nevertheless, quite justifiably at the center stage of cell biology. In contrast to EM analysis, which always presents snap-shots of processes, video analysis by LM can allow one to see dynamic events in real time within cells. One of the "take-home" messages of this review is to point out that for modern cell biology studies one needs *both* LM, to see an overview of the "forest," and EM to see the details of the "trees." I will try to demonstrate that state-of-the-art EM methods should be standard technology in all laboratories involved in molecular cell biology research. It should also be pointed out that the expertise needed to execute these methods at the highest level is rapidly dwindling, as fewer specialist groups are available to keep these methods alive. I hope this chapter will also contribute to an awareness that this situation can, and must, be reversed.

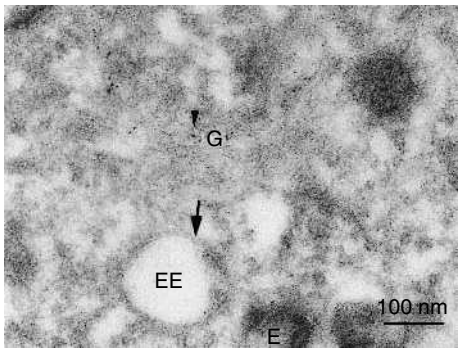
1.1.1 **The Strategy**

The spectrum of EM techniques of interest to cell biologists is quite broad. For each method, one can easily write a whole book, and many books are indeed available. Several of these methods are technically quite demanding. Given the space limitation and the need to cover almost all techniques, the approach I have taken is to explain the basic concepts behind each approach so that a total beginner could understand how each technique operates and what it is good for. For the most commonly used methods, photographs, and schematic diagrams are provided to show those details that are important for the method to work.

The strategy I have followed is to start with live cells or organisms, or isolated biological material in an aqueous solution and describe the two fundamentally different ways of preparing these specimens for transmission – EM-conventional chemical methods, and the cryo-based approaches. Some of these conventional methods, as well as one partly cryo-approach, can be used for the detection of antigens using



(a)



(b)

Fig. 1 Comparison of LM and EM. (a) Shows an immunofluorescence micrograph showing labeling for a trans-Golgi protein sialyl transferase. A Hela cell line stably transfected with a construct containing sialyl transferase tagged with a domain from the vesicular stomatitis virus G-protein (provided by Tommy Nilsson) was fixed with 3% formaldehyde followed by a permeabilization with 0.1% Triton X-100. The cell was then labeled with a rabbit antibody against G-protein tag followed by a secondary antibody coupled to rhodamine. The typical ribbon-shaped appearance of the red Golgi complex is evident, next to the nucleus. The latter is revealed using DAPI staining for DNA that was done at the end of immunolabeling reaction. (b) Shows a Tokuyasu cryosection of the same specimen labeled with the same antibody and protein-A gold (arrowhead). Note the significant amount of labeling on the trans-side of the Golgi. There is also sparse label on membranes of some endocytic structures (E). EE – represents the early endosomes, evident by their sparse labeling for 5 nm gold-BSA (arrow) that was internalized for 5 min before fixation. Bars = (a) 10 µm and (b) 100 nm. Micrographs courtesy of Veronika Neubrand and Anja Habermann. (See color plate (p. xxii).)

immunogold labeling; the essence of these methods will be covered.

At the end of these preparation methods, the specimens are placed on an EM grid. The two different ways of imaging these specimens at room temperature or using a cryostage are then described. A recently perfected approach for obtaining three-dimensional models from a series of tilted images by tomography will next be summarized, followed by two sets of methods that visualize (mostly) surface structure, namely freeze-fracture (etching)/replica methods for transmission electron microscopy (TEM) and low- and high-resolution scanning EM. The ability to use scanning transmission EM (STEM) for mass determination and X-ray microanalysis for the detection of some ions will be briefly mentioned. The powerful use of stereology to quantify structural parameters from sections will then be outlined. Following a brief description of methods that can be used to correlate LM with EM data, and a note of caution about interpreting thin section images, I end by offering some guidance on which technique is appropriate for which scientific question.

2
Specimen Preparation

Before a specimen can be visualized by transmission EM, it must fulfil a crucial criterion – it must be *very thin* (less than about 0.4/0.5 μm) for electrons to pass through it. In all transmission-EM approaches, the specimen is mounted on a 3-mm diameter metal (usually copper) grid (0.01 mm in thickness). This supports the specimen between the grid bars and allows electrons to pass through the specimen that lies across the holes in the grid. The grid is usually covered with a thin plastic film (such as formvar or collodion) and preferably coated with a thin layer of evaporated carbon before attaching the specimen. This provides stability by reducing surface charge buildup. The evaporator is a prominent machine in almost all EM laboratories.

In practice, there are two different possibilities for adsorbing the specimen onto the grid. If the specimen is particulate, that is, a discrete entity that is no larger than, at most 0.5 μm in height, it can be directly adsorbed onto the grid. Thin regions of whole cells grown on EM-grids can also be analyzed this way, using a newly developed cryo-EM approach (see Sect. 6.1 on Tomography, below). If, however, the structure is larger or, more commonly, one wants to see structures inside organelles, cells, or tissues, one must embed the specimen, or solidify it by vitrification, and then cut thin (usually 50–300 nm) sections. An alternative approach is to freeze-fracture the specimen and analyze the fractured surface, or after etching, the subsurface topography. Both TEM and scanning electron microscopy (SEM) can be used to visualize these specimens.

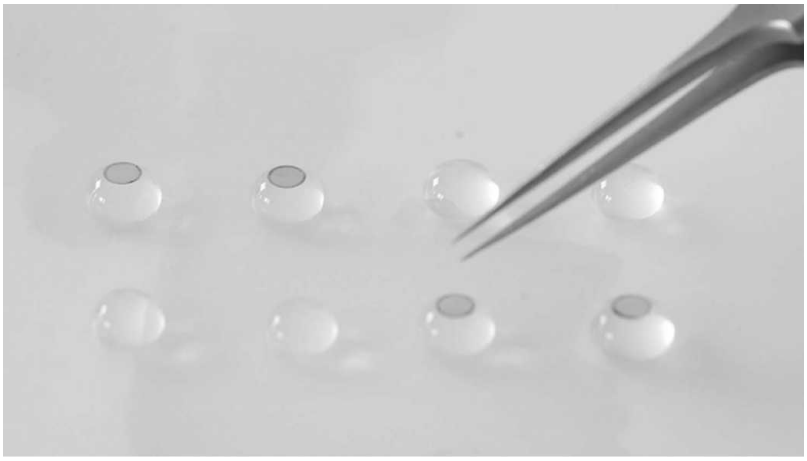
The key to the analysis of any cell structure, at any scale, is the ability to ''fix'' the structure, either by chemical cross-linking, or, more preferably, by arresting it physically in its aqueous environment by freezing. Although chemical fixatives have been used successfully for EM since the early 1940s (see Fig. 17), the introduction of the concept of cooling into the vitrified state has now emerged as the fundamental innovation in EM-specimen preparation. The ability to vitrify a specimen within milliseconds, in conjunction with a physical proof that the specimen is indeed in a vitreous state, now offers the best possible method that provides a fundamental frame of reference for all EM-specimen preparation methods.

Native biological material is extremely fragile and sensitive to electron beam damage. For this reason, a series of methods have been developed to optimize specimen preparation, the *sine qua non* of all EM. While one kind of approach, environmental SEM (ESEM) is starting to provide a means of imaging specimens (such as whole cells) in their aqueous environment, this is still in its infancy. This approach will not be discussed further here.

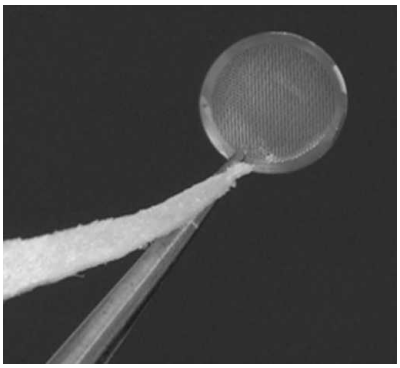
3
Ambient Temperature EM Methods

3.1
Negative Staining of Particles

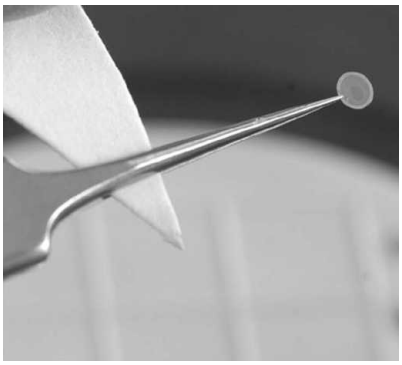
The simplest and most rapid approach in EM is ''classical'' negative-staining (Figs. 2, 4). This approach is useful for proteins, macromolecular complexes, viruses, (small) bacteria, and isolated organelle fractions. Particles are adsorbed onto EM-grids having a suitable surface. This surface is crucial for success and in most cases the grids are covered



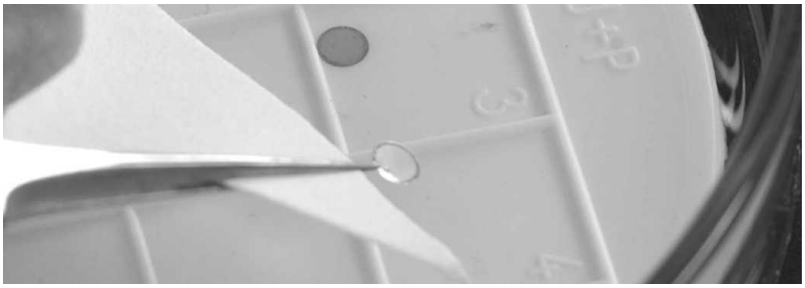
(a)



(b)



(c)



(d)

Fig. 2 Negative staining in practice. In (a) the grids are seen floating on solution, they can be moved from one drop to the next using a fine forceps. (b) After the final staining reaction, the grid is lifted from the drop of stain and a filter paper is used to remove the excess stain; (c) and (d) show a simple trick to cleanly remove the dried grid from the forceps. A triangular piece of filter paper piece is inserted in the forceps and is then used to gently push out the grid cleanly onto a suitable support.

with a layer of evaporated carbon on a suitable plastic film (e.g. formvar). It is often an advantage to ''glow discharge'' grids, a procedure whereby air (in a light vacuum) is ionized by ~500 to 1500 V, thereby making the grid surface hydrophilic (methods are also available to make grids hydrophobic; these are useful for some specimens). Grids are floated on as little as 3 to 5 µL of an aqueous (usually buffered) solution of the specimen for a few seconds to minutes to adsorb the material.

The grid plus absorbed particles are then rinsed rapidly with water and floated on a (1–5%) solution of a heavy metal stain, such as uranyl acetate, sodium phosphotungstate, or ammonium molybdate. If pure water is not desirable, the salts in the buffer (which will react with the heavy metals) can be removed by many rapid changes (1 s each) of the grids on pure stain. After a few seconds to 1 min on the final drop, the grid is removed with forceps and the excess stain is partially removed with filter paper (Fig. 2). A relatively thick layer (~100–300 nm) of stain needs to dry down around the specimen. The staining is referred to as ''negative'' because the stain fills the spaces around the specimen that are seen outlined in negative contrast. Examples are shown in Fig. 4(a–c). Although technically trivial, there are a number of ''tricks,'' and in the hands of specialists, this approach can provide a relatively high level of resolution/information..

This approach (and the positive staining discussed below) is easily compatible with immunogold labeling before the drying step. One limitation is that only antigens exposed on the surface of particles can be labeled. In some cases, the particles can be treated with reagents that can ''open up'' the particle. In one such example, the reducing agent dithiothreitol (DTT) was used to expose antigens that are normally buried within vaccinia virus particles (see Fig. 4b).

3.2 Positive-negative Staining Approaches

The adsorption staining procedure developed by Tokuyasu to protect thawed cryosections from drying artifacts is a powerful alternative method that is easier to control and to image than negative staining, especially for beginners. The method is shown in practice in Fig. 3 and schematically in Fig. 8(g). In this approach, the stain adsorbs to some parts of the specimen (positive staining) and can be seen because of the low background contrast. Some negative-staining effects can also be seen, depending on the specimen and the precise conditions used (see the right virus particle in Fig. 4b). This is expected since heavy metal compounds used for negative staining also positively stain biological structures.

This method has several advantages over classical negative staining. (1) The stain adsorbs to selected structures, usually by ionic interactions. Therefore, the differences in intensity of staining in different parts of the structures provide additional information not available by negative stain methods. (2) The fact that the overall concentration of heavy metal stain over the grid is far less than in negative staining means that beam damage, often a serious problem in negative staining, is far easier to deal with. (3) This means that it is also easier to collect large data sets, as for tomography due to the reduction in beam-induced damage. Images such as the one shown in Fig. 4(b) are currently being analyzed by this approach. Membrane organelles collapse far less than with normal negative staining

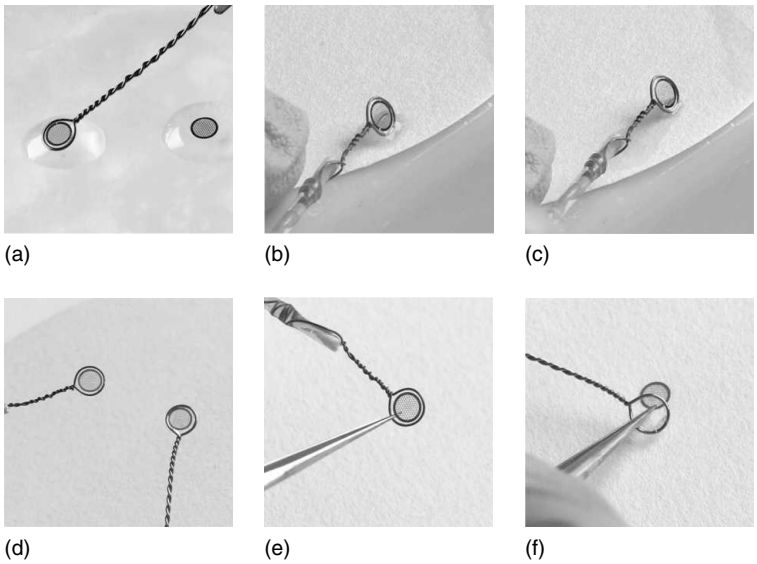


Fig. 3 Methylcellulose embedding in practice shows the basic technique involved in methylcellulose embedding. (a) The grid, having been previously rinsed in distilled water, is placed on a solution of methylcellulose and uranyl acetate on ice. (a–c) The grid is then looped out and the excess stain is removed by touching the loop onto a surface of filter paper (d) The grid is allowed to air-dry. Ideally, the interference colors should be gold, purple, or blue at the end of the technique. (e) and (f) show removal of the grid from the loop.

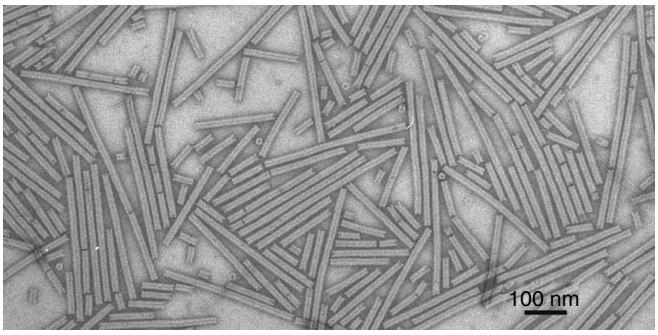
(4) Finally, by varying the concentration of the stain, one has the possibility in the Tokuyasu approach to vary the physical appearance of the particle; for example, locally high concentration of uranyl acetate over some structures can reveal negatively contrasted thin tubules that are often more difficult to visualize by positive-staining methods. An example is given in Fig. 4(b).

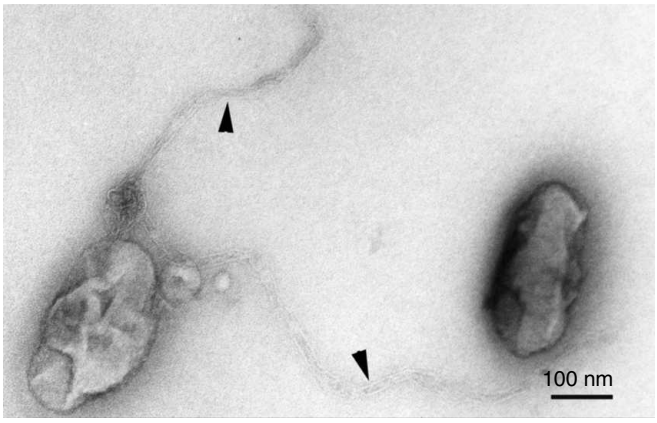
Fig. 4 Examples of negative and positive staining for EM. (a) Shows a classical negative staining using phosphotungstic acid of tobacco mosaic virus (TMV). The typical rod shaped appearance of this virus is seen. Some subunits of the virus are also seen end-on. It is evident that these are spherical in profile. (b) Shows vaccinia virus that has been treated with the reducing agent dithiothreitol (DTT). This treatment is known to break disulfide bonds within the virus. The virus was then embedded using the metal cellulose/uranyl acetate mixture as shown in Fig. 3. The increased stabilization of structures and the partly positive staining by this procedure allows more details of this relatively large virus to be seen. The arrowheads indicate two round tubular projections that have been ejected from the core of the virus by the DTT treatments. We believe these may facilitate virus entry into cells during infection. The particle on the right shows a side-view of another particle. In (c), the same virus preparation can be seen after conventional negative staining using uranyl acetate. Less fine detail is evident after this approach. Nevertheless, the areas where stain enters the particle can be delineated by the heavy metal stain. The arrowheads indicate apparent openings between the virus and the core of the particle. Bars = 100 nm. (a) – Courtesy of Heinz Schwarz; (b) and (c) – from the author.

3.3 Classical Resin Embedding

The majority of thin section analysis worldwide is still carried out using room-temperature specimen preparation techniques in which chemical fixatives, especially glutaraldehyde, are applied. These approaches are structurally acceptable in so far as the structures they describe have been observed by a cryobased approach; this statement is reasonably valid for all known organelles. For new structures, their acceptance should



(a)



(b)

(c)

be based on confirmation by a cryobased approach, such as freeze-substitution or using hydrated cryosections.

By far the most widely used approach for ultrastructural analysis today, as it has been for the past 50 years, is the epoxy resin method. This is a witch's brew of empirically determined steps for converting fresh tissue, cells, or isolated organelles into a thin section. Although the variety of recipes is greater than in most cookbooks, the general principle is as described below. For analyzing repeatedly the same cells or tissues whose ultrastructure is well known, as in pathology, the conventional plastic-section approach is still the method of choice in most laboratories. Many useful textbooks on EM can be found in many established EM laboratories around the world (usually collecting dust!).

3.4 Chemical Fixation

Glutaraldehyde is the chemical fixative of choice for preserving structure for conventional EM. The introduction of this fixative was, without doubt a revolutionary innovation for EM in cell biology; a number of organelles, such as microtubules, were first seen only after they could be preserved with this reagent. It is a powerful cross-linker of amino groups, especially in proteins and amino-lipids. Although the chemistry involved in this process is very complex, and complicated more by the fact that the cross-linking coincides with the process of cell death, in practice it is very simple to apply the fixative to any "open" cell system; that is, cells that are accessible to a solution without having a barrier, such as a cell wall or a cuticle to block access. If cells are growing in culture, the best results are usually achieved by adding the fixative to the growth medium directly, for the first few minutes, and then switching to buffered fixative. Any barrier to the solutions, such as cell walls, must be dealt with on an individual basis. The best advice is to check how others have prepared the cells of interest. If one wishes to fix a tissue *in situ* in an animal, the best procedure is usually *perfusion*, a nontrivial surgical operation. It is important to respect the old rule of thumb that, for optimal results, the specimen pieces should be less than 1 mm in all dimensions to ensure good penetration of reagents.

When immunolabeling, as opposed to purely structural analyses, is the goal, it is often the case that extensive cross-linking with glutaraldehyde will tend to sterically hinder the access of antibodies to the antigens. A weaker cross-linker, formaldehyde (which, in solution becomes methylene glycol) is therefore used for this purpose, either by itself, or in combinations with (lower concentrations of) glutaraldehyde. For example, in standard protocols for the Tokuyasu method (see below), cells are fixed for 15 to 60 min in 4% formaldehyde and 0.1 to 0.2% glutaraldehyde followed by an overnight (or longer) fixation in 4% formaldehyde in a suitable buffer.

Aldehyde cross-linking generally is a process that releases protons. This lowering of the pH within cells is unlikely to be protected by the buffer since all the routinely used buffers are charged molecules that are thought to enter cells very inefficiently. The cross-linking reactions also consume oxygen.

Although this approach can provide a faithful presentation of ultrastructure, there are many known examples of specimen preparation–induced artifacts. This

usually becomes evident when a less-perturbing cryobased method is used. A classical example is the bacterial "mesosome"; earlier considered a distinct organelle, it is now known to be a fixation artifact, from the use of hydrated cryosections. Another striking example of aldehyde-induced artifacts in the frog retina revealed by high-pressure freezing and freeze-substitution has already been written about.

3.5 Postfixation

For pure structural studies, but generally not for immunolabeling, the aldehyde fixed tissue is "postfixed" in (0.5–1%) osmium tetroxide (OsO_4). One of the very first micrographs using this fixative for EM is shown in Fig. 16. This heavy metal can cross-link lipids and protein and adds general contrast to many organelles, especially membranes (enhancing the trilaminar appearance). It is also clear that artifacts may be induced, the most striking being the proteolysis of structures such as actin filaments. It is generally accepted that, when used at the low temperature for freeze-substitution (see below), the use of OsO_4 is generally free of artifacts and is a useful addition to enhance contrast. As pointed out below, OsO_4 is generally incompatible with the polymerization of many resins used for immunolabeling (such as lowicryl). Concentrations up to 1% in the freeze-substitution schedule may be used without interfering with UV polymerization of these resins. Osmium can also be successfully used with LR white (see below) (see Fig. 7). Many workers add a second postfixation step after the OsO_4 using uranyl acetate, which binds to negatively charged phosphate groups in phospholipids, is generally an excellent stabilizer of lipids. Tissues are often left in aqueous solutions of this stain for, for example, 1 h; an alternative so-called *en bloc* procedure that we often use is to leave specimens overnight in a saturated solution of uranyl acetate in 70% ethanol prior to embedding.

3.6 Dehydration and Embedding

The epoxy resins (e.g. Epon, Spurrs, Araldite) are highly hydrophobic, while many of the methacrylates have a lower hydrophobicity, but are still immiscible with water. For this reason (as in paraffin embedding for histology), the water must be replaced (gradually) with an ascending series of ethanol or acetone (which tends to extract more material than ethanol). At the 100% solvent stage, the resin is gradually mixed with the solvent over a period of a few hours until it can be placed in pure resin. At this stage, the specimen in resin is mounted into an embedding mold (Fig. 5b) or other suitable container (e.g. BEEM capsule) and left overnight at room temperature (at which little polymerization occurs) for complete infiltration, before being allowed to polymerize for about 12 h at 60 to 70 °C. The specimen is now ready to section. The standard epoxy and araldite resins are quite viscous and it is often a problem to penetrate some specimens, such as many plant and insect tissues. In 1969, Arthur Spurr introduced his concoction, known as *Spurr resin* as a low viscosity epoxy resin alternative. This has become the standard resin for many specimens. Alternative low viscosity–embedding media are now also commercially available. For more details there are many classical textbooks available in EM laboratories. For an example of

an image of an epoxy resin section, see Fig. 6.

3.7 Methacrylate-based Embedding

After the introduction of the complete Tokuyasu method in 1978, this approach was the section method of choice for immunolabeling. For the next two to three years, all alternative embedding protocols were far inferior for this purpose. However, in 1980 appeared the first in a series of papers from Eduard Kellenberger's laboratory in Basel, in which an excellent alternative approach became available. After years of painstaking work in collaboration with an industrial partner (Lowi), Carlemalm et al. were successful in introducing the first of the Lowicryl resins, the more hydrophilic K4M, and the more hydrophobic HM20. Its great potential for immunogold labeling was shown already in the first publication. The basic approach is no different to the epoxy protocol outlined above; it is simply a question of which solutions, in which order, and for how long. However, the resins are polymerized by UV light rather than by heat.

Although these resins can be used at room temperature, the goal from the outset was to develop these resins predominantly for use at low temperatures. In the initial publications, an approach known as *progressive lowering of temperature* (PLT) was introduced. Here, starting at the dehydration step, the temperature is gradually lowered to $-35\,^{\circ}C$. The importance of these resins is that they can be polymerized at this temperature using UV polymerization (although they can also be polymerized by heat). This polymerization usually takes one to three days and often the blocks need additional curing time at room temperature in direct sunlight (without glass).

In 1985, this group introduced new resins (K11M) that could be polymerized down to $-60\,^{\circ}C$ and HM23, which will polymerize even at $-80\,^{\circ}C$. These became especially useful in combination with freeze-substitution (see below, and Figs. 13, 15b). The important contributions of Bruno Humbel and Martin Müller toward this approach should also be mentioned.

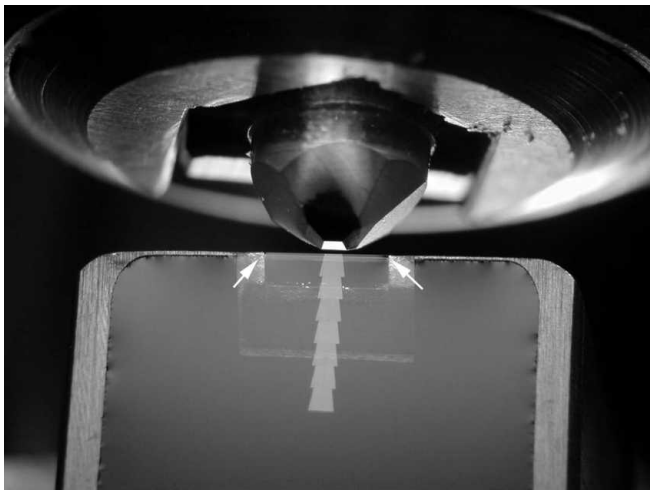
In England, Brian Causton, a chemist, in conjunction with the London Resin (LR) Company, developed an alternative set of resins LR white and LR gold. These resins are now widely used for EM immunolabeling, especially in laboratories that lack

Fig. 5 Plastic sectioning for EM. In (a), a trimmed Epon block is shown in a Leica ultramicrotome being sectioned on a Diatome diamond knife. The 2.5-mm knife-edge is indicated by arrows. A ribbon of sections is seen. This ribbon is only slightly longer in length than the diameter of an EM grid. Normally, one would tease this ribbon away from the knife-edge using a fine eyelash. The grid is then lowered carefully, film side down, onto the ribbon and pressed gently. The grid is ideally rotated on the surface of the water so that the water can run off smoothly from the surface of the grid. The grid is then raised and air dried. An alternative method that avoids section wrinkles is to dip the grid into the water beneath the sections and then carefully raise the grid at about a 45° angle to fish the ribbon. Photograph courtesy of Robert Ranner Leica Microsystems GmbH, Vienna. (b) Shows specimens that have been polymerized in an embedding mold. The specimens are black following osmium treatment (arrows). A piece of paper with specimen details can be conveniently coembedded with the specimen. Courtesy of Anja Habermann and Maj Britt Hansen.

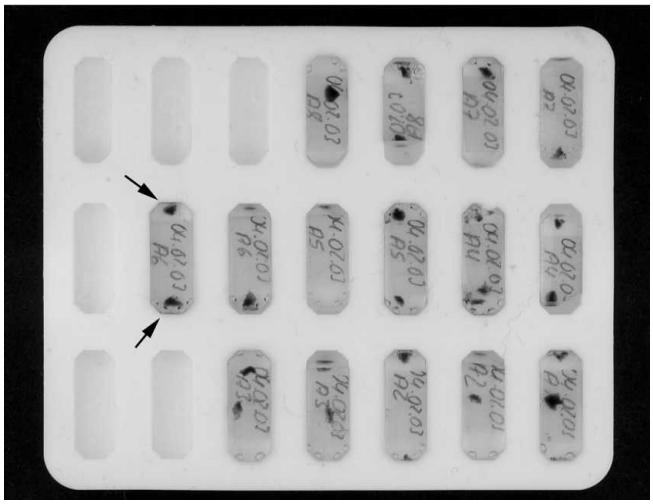
the equipment for cryosectioning. As mentioned, LR white is also compatible with osmium tetroxide treatment and recipes exist for providing beautiful preservation in conjunction with immunogold labeling (Fig. 7).

All the methacrylate-based resins are sectioned in the same way as other plastic-embedded blocks (Fig. 5a). For the more hydrophilic ones, such as Lowicryl K4M, the water level in the trough of the knife boat (Fig. 5a) needs to be lowered, compared to Epon sectioning, to prevent the sections being pulled behind the knife.

All the resins used for EM are potentially toxic, as are the fixatives and appropriate caution should be taken when handling



(a)



(b)

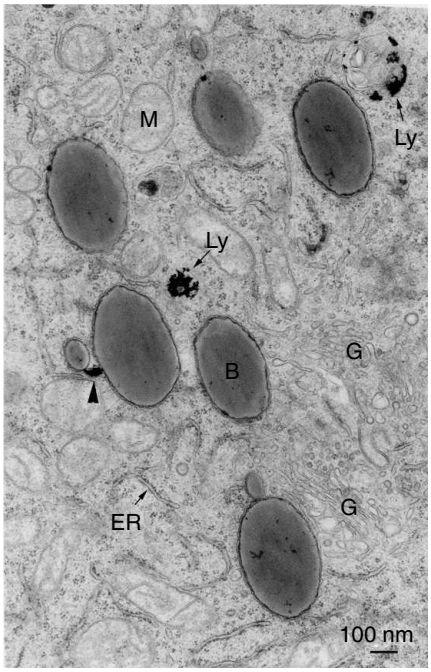


Fig. 6 Example of an epoxy resin section. This shows a section of a J774 macrophage that had internalized BSA-conjugated gold particles for 1 h followed by a chase in medium free of gold for 1 h. Under this condition, the gold is in late endosomes and lysosomes (Ly). Subsequently, 1-µm latex beads (B) were added for 1 h followed by a further 3-h chase. Gold can be seen in late endocytic organelles and in the latex bead phagosomes (arrowhead), after a fusion process. Other organelles, Golgi stacks (G), mitochondria (M), and ER are indicated.

them (eye protection, gloves, hood, etc.). Particular care should be taken when working with the Lowicryl resins that are well known to cause skin problems.

3.8 Plastic Sectioning

The specimen embedded in plastic must next be trimmed to make a small block that can be pyramidal or rectangular at its tip (usually 0.01–0.1 mm, see Fig. 5a). This can be done manually with razor blades but is much more precisely done using commercially available block trimmers that have metal or diamond blades.

The trimmed block is next mounted in an ultramicrotome equipped with a glass knife or, more conveniently using a diamond knife (Fig. 5a). The combination of modern ultramicrotomes and state-of-the-art diamond knives now enables sections as thin as 20 nm to be easily and reproducibly obtained.

As shown in Fig. 5(a), during plastic sectioning, the sections are floated on the surface of (clean) distilled water where they can be manipulated with an eyelash and mounted on a carbon and plastic (e.g. formvar) coated grid. In this simple procedure, the grid surface is brought into contact with the sections, which are adsorbed. The sections are routinely stained by floating the grids on a solution of, first uranyl acetate (which may not be necessary if it was included before embedding), and second with a solution of lead citrate (for a few minutes only) (see Fig. 2a). After rinsing with water and air-drying, the grids are now ready for imaging.

When immunogold labeling is desired, sections of methacrylate-embedded material can be labeled, as described below. In this case, the staining with

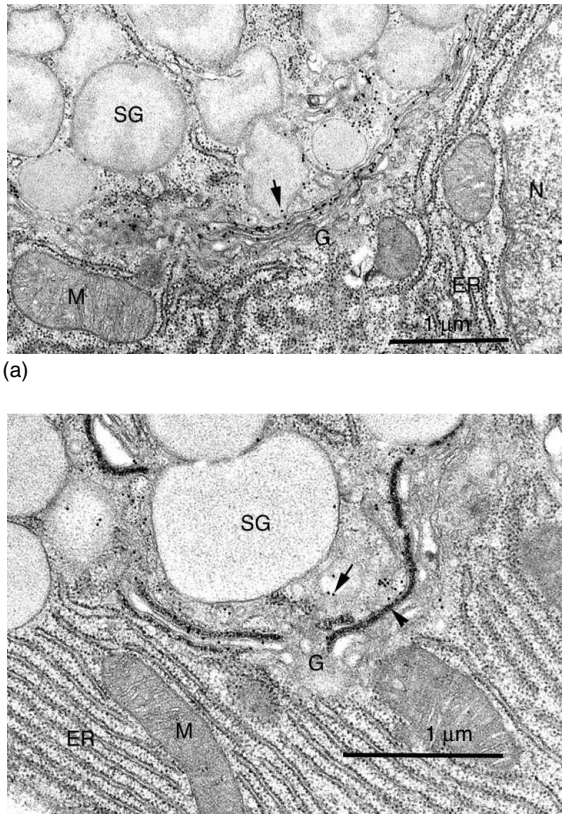

Fig. 7 Example of embedding in LR White. (a) and (b) show rat parotid acinar cells embedded in LR White. Pieces of parotid tissue from a rat were fixed in a mixture of 0.5% glutaraldehyde and 4% formaldehyde under microwave irradiation, followed by postfixation with 1% osmium tetroxide containing 1.5% potassium ferrocyanide (reduced osmium) under microwave irradiation and continued for 30 min on ice. Tissue blocks were embedded in LR White resin, and ultrathin sections were obtained. The ultrathin section mounted on a nickel grid was pretreated for etching by a saturated aqueous solution of sodium metaperiodate for 30 s, followed by treatment in 1% bovine serum albumin. Immunolabeling was carried out using anti-GF-1. GF-1 is a monoclonal antibody recognizing 105-kDa glycoprotein in the Golgi apparatus of serous exocrine cells. Colloidal gold particles (arrow) can be recognized to distribute on the trans-cisternae of Golgi apparatus (G). The cells in (b) were additionally reacted for the trans-Golgi enzyme thiamine pyrophosphatase (TPPase) subsequent to the primary fixation. This reaction product is seen as an electron-dense precipitate in one trans-Golgi cisterna (arrowhead in (b)). The sections were labeled with an antibody GF-1, revealed by immunogold. The gold particles are seen to be restricted to the trans-side of the Golgi stack, colocalizing with the TPPase reaction product (arrowheads). The ER is indicated, as are the secretion granules (SG), the nucleus (N) and mitochondria (M). Micrographs courtesy of Shohei Yamashina.

heavy metals is carried out *after* the immunolabeling. An advantage of this approach for immunolabeling is that the room-temperature cut sections can be stored dry on grids indefinitely and still be immunolabeled when desired. These sections can also be powerful tools for use at the immunofluorescence level.

3.9 The Tokuyasu Sucrose Embedding – Cryosection Method

An elegant and rapid method for visualizing structure and immunolabeling using cryosections was pioneered by Tokuyasu between the late 1960s and 1978. This is now used extensively worldwide.

In contrast to the hydrated cryosection method (see below), there are two severe restrictions in obtaining cryosections for immunolabeling, in addition to the obvious need for the cryomicrotome. One is that immunolabeling needs to be carried out above 0 °C and the other is that ultrathin cryosections of fresh specimens are destroyed when thawed. For this reason, the specimen must be chemically fixed prior to sectioning, usually with a light, fixation protocol (see above).

So, the role of the sectioning process in this approach is simply to be able to cut thin sections of fixed cells and tissue that can subsequently be immunolabeled while fully hydrated at ambient temperature. While this may be a disadvantage for high-resolution preservation, it also offers a number of practical advantages in comparison to the hydrated cryosectioning method. First, because the material is chemically fixed, the membranes are permeable to high concentrations of sucrose, which is an excellent cryoprotectant. This means that relatively large pieces of specimen (>1 mm^3) can by *vitrified routinely* by simple immersion in liquid nitrogen (which is a relatively poor coolant). Moreover, sucrose (up to 2.3 M) allows the specimen to be more easily and uniformly thin sectioned in a cryoultramicrotome at, for example, −100 to −120 °C. So, although the method involves a vitrification step, it cannot be considered a *bone fide* cryo-EM method. Nevertheless, it is mostly referred to as the cryoimmuno-EM method. The steps in this method are shown schematically in Fig. 8.

The trimmed specimen is cut with a glass knife, or now more commonly the superb new generation of diamond knives designed for cryosectioning. The temperature is usually in the range of −90 to −120 °C. At these temperatures, water obviously freezes and a major difference between cryo and plastic sectioning is that cryosections are cut on a dry knife (i.e. no water trough). The colder the specimen, the harder the block; for cutting sections for LM, the blocks are made softer by raising the temperature from −50 to −80 °C. Many workers also raise the temperature of the block to −80 °C for trimming the block before cutting thin sections at colder temperatures. Plasticity of the block is also an important parameter to vary for optimal sectioning properties, and compounds such as polyvinyl pyrrolidine can be added to the sucrose infusion in order to facilitate the sectioning process. At all temperatures, even the best sections are initially compressed. They are then picked up using a 1- to 2-mm loop of thin wire that contains a drop of 2.3 M sucrose (Fig. 8d). The sucrose drop is rapidly brought into the cryochamber and, upon contacting the sections and brought to room temperature, it decompresses; a spherical cell profile that is significantly compressed after sectioning can now regain its spherical shape. Often, this method leads to overstretching of the sections, causing structural artifacts. For this reason, the use of a mixture of sucrose and methylcellulose was introduced, which could greatly improve structural preservation (see Figs. 1b, 9, 14). Tokuyasu (personal communication) considers the osmotic pressure to be an additional important factor in section pickup. To reduce the impact of high osmotic pressure, the use of a mixture of 1.7 sucrose solution with the detergent Tween 80, at a final concentration of 0.01% to retrieve cryosections embedded in 2 to 2.3 M sucrose was recommended; we have found this approach to be very useful. Section compression can also be minimized by reducing the sectioning angle

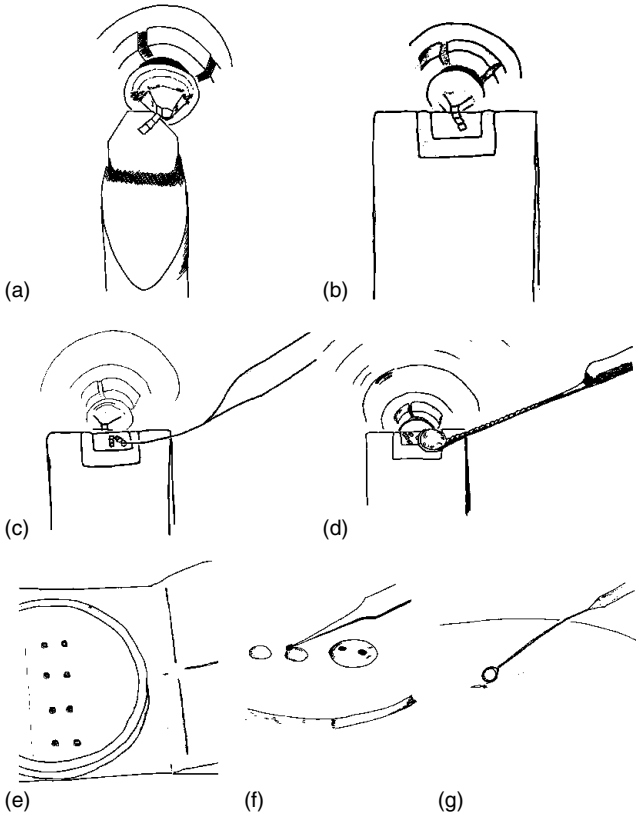

Fig. 8 Schematic illustration of the Tokuyasu method. These drawings, made by Paul Webster, illustrate the basic essential details of the Tokuyasu cryosectioning and labeling method. All steps are carried out within the chamber of the cryoultramicrotome. Prior to step (a), the specimen will have been fixed, infused with sucrose, and placed on a specimen pin. (a) Shows the procedure for trimming the block using a trimming device. Glass knives or special diamond trimmers can also be used for this purpose. In (b), the specimen is sectioned on a glass or, in this case, a diamond knife, and the sections are manipulated using an eyelash probe (c). In (d), the sections are picked up on a loop containing 2.3 M sucrose or a mixture of sucrose and methylcellulose. The loop is then touched onto the surface of a grid and the grid is raised and allowed to be floated (section surface down) on a drop of liquid. (e) Shows the procedure for maintaining a moist chamber around the grids. A petri dish is then layered over the grids, and a piece of moist filter paper is added on one side of the petri dish; (f) and (g) show again the principle of drying the grid after embedding in a methyl cellulose mixture (see also Fig. 3).

of the diamond knife. A new oscillating diamond knife is being developed that already looks highly promising in reducing this problem even further.

Once the sections are thawed on the surface of the drop of sucrose (or the mixture with methylcellulose), the loop is brought to the surface of an EM grid and, upon contact the sections are transferred to the grid surface. From now until the final drying step, the fragile sections must remain hydrated and not be allowed to dry. The universal procedure for immunogold labeling can be applied (see below). It should be noted that in addition to its use for immunolabeling, this method is also an excellent and rapid (1–2 h) method for preserving and visualizing structures in thin sections by EM. It is surprising that this method has not been more widely used, for example, in pathology, as a rapid diagnostic tool.

Either with or without immunolabeling, the final step in the preparation is to dry/embed the sections. Since, as mentioned, the sections are easily destroyed by air-drying, Tokuyasu spent a number of years developing what in the end turned out to be a surprisingly simple approach to protect the sections from collapsing during the drying process. His elegant solution was to float the grids with sections (that were previously floating on pure water) on a mixture of heavy metal stain (usually uranyl acetate) and a polymer (usually methylcellulose, this is more soluble in the cold) for a few minutes. The grids are then looped out using a ~3.5-mm loop, the excess solution is removed by blotting and the grid is air-dried/embedded (Figs. 3, 8). After removing the grids from the loop with a forceps, they can be visualized by EM. This simple procedure revolutionized the use of thawed cryosections for immunolabeling at the EM level.

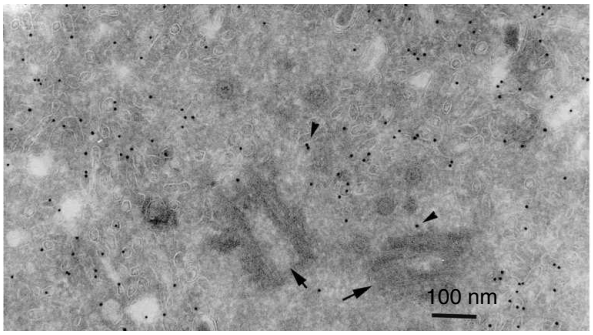
3.10 On-section Immunogold-labeling Procedure

The localization of specific antigens on isolated particles, or on thin sections can be performed using immunogold-labeling methods. A theoretical drawback of these methods is the need to label the specimen at physiological temperatures, which limits their use for *bone fide* cryobased approaches. Nevertheless, these methods have been very powerful in a

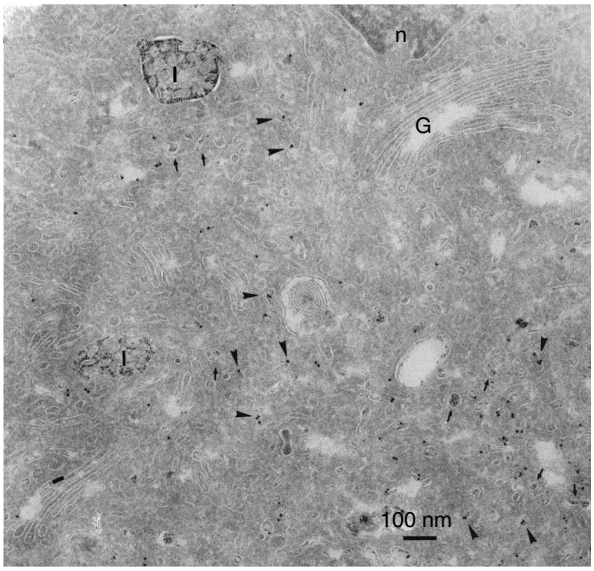
Fig. 9 Example of using the Tokuyasu technique. These images show cryosections of glutaraldehyde-fixed Chinese hamster ovary (CHO) cells showing the distribution of Prion protein using an anti-PrP C monoclonal antibody Fab fragment (R1). (a) Gold labeled PrPC (arrowheads) was found to be highly enriched in the caveolae at the plasma membrane (PM) (not in this picture) and caveolae-containing membrane structures in the trans-Golgi network (TGN) around the pericentriolar region; arrows pointing to centrioles. (b) Endocytosed 5-nm protein-A gold particles (which bind specifically to PrPC; arrowheads) indicate the sites of PrPC molecules that had been taken up via caveolae. These results indicate that typical early endosomes do not intersect significantly with the endocytic pathway of PrPC-containing caveolae. In addition to the typical small tubulo-vesicular structures, many larger multivesicular-bodies (late endosomal/lysosomal profiles, L) were loaded with small gold particles representing endocytosed PrPC, whereas the transferrin receptor (labeled with an antibody and large, 10 nm, gold) localized in nearby and distinct structures. As expected, ER, Golgi complex, mitochondria, and nucleus were not labeled, indicating highly specific labeling in these experiments. G: Golgi complex, n: nucleus. Micrographs courtesy of Peter J. Peters.

wide spectrum of molecular cell biological applications.

The essence of all immunolabeling is the same for all procedures at the LM and EM level. However, the use of sections (for LM or EM) obviates the need for a permeabilization step (see below). Subsequently, a minimum of three incubation steps is required, along with rinsing steps. The first step is to *block nonspecific sites*. All proteins (some more than others) have the capacity to adhere to (most) surfaces and it is generally thought that this is due mostly to ionic and hydrophobic interactions. In practice, one can usually (but not always) block these sites on the sections (and grid) surface by simply floating the grid on a drop of a suitable protein solution for a few minutes. Many groups use different kinds of sera (e.g. goat serum) for this purpose, in which case one must be sure that this does not interfere with the immunolabeling reaction. We prefer to



(a)



(b)

use a mixture of fish skin gelatin (from an arctic fish, via the Sigma company) and bovine serum albumin. Whatever one uses, it is recommended to dilute the antibodies and gold reagent in this solution for the subsequent labeling steps. In practice, the whole labeling procedure is most conveniently carried out on the surface of a layer of parafilm (see Fig. 2a).

3.10.1 **Step 2 – Antibody Labeling**

The grid floating on the block solution is transferred to the surface of a 5- to 10-μL drop of the ''optimal'' dilution of antibody in the blocking solution and left for 30 to 60 min in a humid chamber on the parafilm surface (see Fig. 2a).

The problems of antibody specificity must be seriously considered in evaluating EM (as for LM) immunolabeling. It is important to note that apparent proof of specificity by an immunochemical approach such as Western blotting does *not* necessarily constitute proof of specificity on the surface of a thin section since the conditions facing the antigen are quite different. It is crucial to realize that the complexity of possible interactions on the surface of a section can give rise to subtle and serious artifacts that may fool the observer. It is also important to realize that the numbers of antigens available at the surface of thin sections can be deceptively low.

It is crucial to determine the optimal concentration of antibodies for the best signal-to-noise ratio. Above this level, background labeling can increase significantly. The simplest take-home message to achieve this is to empirically determine the highest concentration of antibody (which, in some cases, may even mean undiluted antibody!) that does not label structures assumed to be free of antigens. The foundation of this assumption is the available cell biological knowledge on the system.

Depending on the gold reagent that will be subsequently used, one may need to use a secondary antibody step. For example, if one uses protein-A gold (which is the preferred reagent in many groups, including ours), and one starts with a mouse antibody (that mostly do not bind protein-A), then an intermediate step of, for example, rabbit anti-mouse is required before applying the protein-A gold. Before and after such a step, a series of rinses on drops of, for example, phosphate-buffered saline (PBS) is required for 10 to 15 min. Alternatively, one can use a secondary antibody conjugated to gold (see below).

3.10.2 **Step 3 – Gold**

After the rinses following the last antibody step, the grids are floated on the empirically determined concentration of protein-A gold or an IgG gold conjugate. These conjugates can be easily made in the laboratory or, they can be obtained from many commercial suppliers. In the absence of prior information, the optimal concentration of the gold reagent is the highest concentration that gives negligible labeling in the absence of a primary antibody on the sections that have been exposed to blocking solutions.

Colloidal gold particles consist of pure gold, made by reducing gold chloride ($HAuCl{\bullet}2H_2O$). A number of methods for preparing these colloids have been around since the days of Michael Faraday but the method of choice now is that introduced by Slot and Geuze. By a simple procedure involving citrate and tannic acid this method produces uniform, spherical particles of any size between about 3 and 17 nm; up to three different sized particles can be routinely used for triple labeling studies. Many proteins

can be adsorbed fairly stably (but mostly noncovalently onto the surface of gold particles), without loss of activity; the most useful (in our experience) is protein-A. The noncovalent interactions of proteins and other compounds with gold is complex and highly unpredictable; one must be aware of the possibility that any compound bound to gold may elute from the particle surface with increasing storage time. Procedures for single and double labeling have been described. Following the gold incubation, the sections must be rinsed extensively (~15–20 min) and all salts must be washed away with (preferably double or triple) glass-distilled water prior to final contrasting with uranyl and/or lead salts. The basic procedures for plastic and cryosections are described above. It should also be noted that any particulate material that can be adsorbed to grids can be labeled, but on their outer, solvent accessible surfaces. Only if the structures can be ''opened up'' in some way can one potentially access internally localized antigens.

3.11 Preembedding Labeling Methods

Whereas most EM labeling protocols these days is done using thawed cryosections or methacrylate sections, there is an alternative set of methods referred to as *preembedding labeling* that may be preferred for some applications. The principle here is to start with whole cells or tissue slices (e.g. 20–50 μm thick cryostat or vibratome or tissue/chopper fresh sections) and then treat the material with a solvent or detergent (or even by freeze-thawing) that removes parts of membranes in order to allow antibodies to diffuse into the cell interiors. One simple method that we often use is to put the live cells into distilled water and observe them by light microscopy. When the cells burst (usually after about 10 sfor cultured mammalian cells), fixative is added. In this approach, as in all preembedding methods one accepts structural damage at the outset.

One attraction of the preembedding approach is that at the end of the labeling procedure, the cells are embedded in conventional epoxy resins, that is, technology available in every EM lab for cell biology. Since the ultimate goal is to see the sites of antigens in the context of cell ultrastructure, it is essential to chemically prefix the material before labeling. However, this raises a practical dilemma; if cross-linking is too effective, the antibodies fail to reach many antigens. If, on the other hand, one cross-links too little, cellular ultrastructure is compromised. Since one needs to sequentially introduce antibodies and secondary gold reagents, preembedding labeling is a highly empirical and unpredictable method. Nevertheless, when it works, this approach can provide significant information (see Fig. 10).

The essential steps in a typical preembedding protocol are as follows:

1. The cells/tissue slices are fixed lightly, usually with 2 to 4% formaldehyde (often mixed with a low concentration of glutaraldehyde), usually for less than 30 min.
2. For labeling intracellular antigens, the cells are permeabilized, most often with 0.1 to 0.3% of the detergent Triton X-100 for a few minutes. If the goal is to label antigens on the outer surface of cells this step can be left out. This step, in conjunction with step 1, is difficult to control and is prone to induce artifacts.
3. The permeabilized cells are treated with a protein blocking solution (see labeling of sections above) and then with the

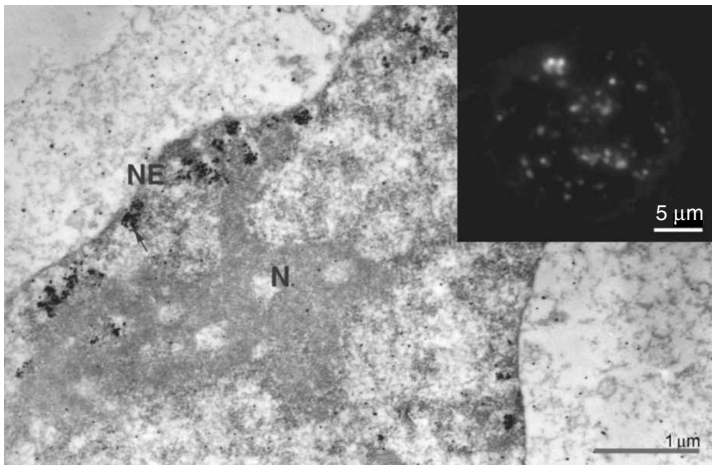


Fig. 10 Preembedding labeling. The replication of chromatin in synchronized HeLa cells has been studied using both light and EM immunodetection. The inset shows individual small fluorescence foci corresponding to DNA replication sites during early S-phase (100 min after release of cells from a double thymidine block of DNA replication). Biotin-16-deoxy-UTP was used as a marker of the newly synthesized DNA. This was delivered into cells by means of hypotonic shift procedure and was visualized by a secondary, fluorescent antibody against biotin. The corresponding EM image is seen in the main figure. For this, the mouse antibiotin was recognized by a 1-nm gold anti-mouse antibody that was subsequently silver-enhanced. The arrow indicates the sites at the periphery of the nucleus (N) where the silver-enhanced gold accumulate, which reflects the DNA replication sites corresponding to the immunofluorescence foci seen in the inset. Micrographs courtesy of Ivan Raska.

optimally determined concentration of antibody (in blocking solution) for periods ranging from 30 min to overnight. The excess unbound antibody must be removed by multiple rinsing steps with buffer (e.g. phosphate-buffered saline, PBS).

4. The cells are incubated with a gold reagent (usually for 30 min to 2 h at room temp) that recognizes the antibody (as for section labeling); also here it is crucial to have the optimally determined concentration of marker. The excess is again rinsed away.
5. The cells can now be fixed with a high concentration of glutaraldehyde (0.5–2% for 30–60 min) in order to protect the structure against the subsequent steps of dehydration and embedding. The remaining procedure is identical to the protocol given above for epoxy resin embedding.

Accessibility of reagents to antigens is often a severe problem in preembedding labeling, with the difficulties increasing as one looks for antigens deeper in the cell, especially within the nucleus. By this approach, a negative result is almost impossible to evaluate; one can never be certain whether or not the reagents had access to the antigens in a defined structure. At the primary antibody level,

antibody fragments such as Fab (which have a significant lower avidity than whole IgG) may improve access. At the gold step, it makes sense to use the smallest sizes of gold. An important innovation here was the commercial availability of 1 to 2 nm gold particles bound with secondary antibodies or protein-A. A number of studies have shown that these penetrate significantly better than 5-nm gold particles. The 1- to 2-nm gold particles are very difficult to see in a typical section. To overcome this problem, metal amplification procedures using silver or gold have long been available and widely used to enhance the size of the gold particles. It should be noted that osmium tetroxide can strip the silver off the gold particles.

At the end of this procedure, thin plastic sections of cells are examined in which gold particles provide an indication of the sites of antigens.

3.12 Immunohistochemical Approaches using Horseradish Peroxidase and Cytochemistry

For preembedding labeling, it is also possible to visualize the bound antibody using a secondary antibody bound to horseradish peroxidase (HRP). This reagent penetrates into cells better than gold particles and has the advantage that the enzymatic properties of HRP can be used to oxidize diaminobenzidine (DAB) into an insoluble polymer that binds Os_5O_4 very well. This cytochemical electron-dense reaction product can be used as an indicator of the site of the antigen. Because of the ability of the reaction product to diffuse, this method is rarely successful for cytoplasmic or nuclear antigens. In the past, it was widely used to localize antigens within the lumen of membrane organelles. However, for a number of reasons, this approach cannot be considered a ''state-of-the-art'' method for immunolabeling.

HRP has also been widely used as a marker of endocytic organelles, and cells will conveniently take up this compound by endocytosis. More recently, cDNAs encoding for this protein as chimeras with different targeting signals have been used to direct the protein to different biosynthetic compartments, such as the endoplasmic reticulum and the Golgi complex. This approach can be very useful to facilitate structural details of these organelles and is likely to be increasingly important as an additional marker for tomographic studies. It has also been used in an interesting method for visualizing endocytic organelles in whole mount cell preparations.

For structural identification of membrane compartments – an old approach – enzyme cytochemistry is still a useful method, although its use has been declining. It is expected that this approach will be used more often for tomographic studies. An example is provided in Fig. 7.

3.12.1 The Use of Microwave Technology for Specimen Preparation

In 1970, Mayers first introduced the idea of using microwaves to enhance the rate and efficiency of fixative cross-linking. Since that time, this approach has become widely used, not only for the fixation step but also for other steps in specimen preparation. Although the precise effects are still not fully understood, specimen exposure to microwaves results in greatly enhanced rates of penetration of chemicals into tissues as well as chemical reaction rates. In the microwave processor, reactions that take hours to occur by diffusion alone can occur in seconds to a few minutes. It is important to note that

standard kitchen microwave ovens are not recommended, since they are difficult to control and, even with short pulses, tend to overheat the specimen. Specially designed laboratory-grade microwave processors are now available that offer variable, controllable wattage and specimen temperatures. Temperature control is achieved in part by circulating large volumes of water through the microwave chamber to remove excess heat. In our group, following the lead of Paul Webster, we now routinely carry out all steps of epoxy resin embedding using this technology. Whereas the overall process used to take two to three days, it can now be completed in a few hours. The microwave oven is also likely to be an important tool in the future for immunocytochemistry by speeding up the penetration and binding rates of antibodies for immunolabeling. Its role in improving antigen accessibility to antibodies is also being exploited. For an example of tissue sections following microwave-assisted fixation, see Fig. 7. It is likely that this technology will play an increasingly important role in many aspects of EM in the future.

4
Cryo-EM Approaches

4.1
Vitrification

The pioneering ideas of Dubochet on the concept of vitrification was the beginning of a new era in EM. The fact that one requires such a thin specimen for TEM allowed Dubochet and McDowall to vitrify a thin layer of water suspended over the holes on an EM grid. Electron diffraction confirmed that the solidified water was not crystalline but remained amorphous. This breakthrough was the culmination of a whole era of studies that were initiated by Fernandez-Moren in the 1950s.

It is estimated that a freezing rate of 10^5 to $10^6\,^{\circ}\mathrm{C\,s^{-1}}$ is required to vitrify water at ambient pressures. No method is known that allows cells (or parts of cells) greater than 10 μm in thickness to be vitrified under these conditions. Only at high pressures can this be achieved to a depth of a few hundreds of microns (see below). Owing to the high rates of cooling that are used, it has been estimated that the process of vitrification arrests the *in vivo* state within $100\,\mathrm{m\,s^{-1}}$ of the final perturbation. For this reason, it has evocatively been described as the ''solidified *in vivo* state.'' There are five different cryo-EM methods we shall discuss: (1) the bare-grid method for isolated particles; (2) hydrated cryosections; (3) freeze-substitution; (4) freeze-fracture and (5) cryo-SEM approaches.

4.2
The Bare-grid Method for Particulate Specimens

Viruses, small bacteria, isolated organelles, filaments, macromolecular complexes, and the like can easily be vitrified. The remarkable consequence of the thinness of these specimens is that an almost trivial procedure allows preparations to be routinely vitrified. Following the innovation to use a perforated film grid support, the method involves suspending the specimen on such a grid mounted in a simple guillotine device. For the best results, the atmosphere around the specimen should be kept humid and specialized devices are now available for this purpose. After a brief blotting on one or both surfaces of the specimen, the grid, attached to a forceps, is rapidly shot into a ~2-cm deep chamber of liquid ethane cooled by an

external container of liquid nitrogen. All the subsequent operations such as transporting, storage, mounting in cryoholders and imaging in the electron microscope, are done at liquid nitrogen temperature to avoid devitrification, which occurs above −135 °C. The imaging of cryospecimens requires special care because highly energetic electrons, while passing through a sensitive specimen, can easily destroy the fine structure. The so-called ''low dose imaging'' has, therefore, been developed (see below). It should be noted that the cryo-EM approach offers the only possibility in EM for visualizing details within the interior of a structure directly. State-of-the-art examples of images obtained by the bare-grid approach are shown in Figs. 11 and 18(a).

This approach has been used for a series of elegant time-resolved analyses, especially by Nigel Unwin and colleagues. For example, the acetylcholine receptor has been visualized in different functional states. The bare-grid approach can also be combined with immunogold labeling and with positive staining using heavy metal salts. This is probably the EM method whose usage is increasing the most in laboratories worldwide.

4.3 Vitrification of Larger Material

The cryopreservation of material larger than 1 μm is a topic that has been extensively investigated. Despite earlier complications, it is now generally accepted that the goal is straightforward; the specimen must be vitrified if it is to provide a faithful reflection of the structure of the *in vivo* state. The hydrated cryosection method (see below) offers the only approach that can allow sections of native material to be evaluated. It is also the only method for unambiguously confirming, via electron diffraction, that the vitreous state has indeed been achieved; although large hexagonal ice crystals can be seen directly without diffraction, the presence of the intermediate cubic ice crystals (up to ~300 nm) cannot. These can also damage specimens.

There are different approaches for vitrifying a layer of biological material thicker than 1 μm; one can consider the more traditional methods such as (1) plunging in ethane or propane; (2) jet freezing; (3) slam-freezing on a cooled silver or copper surface. There is now a consensus that all of these approaches unfortunately, fail in practice to give a layer of vitrification that is more than 5 to 10 μm.

A relatively old method, *high-pressure freezing*, first introduced by Moor, has recently emerged as *the* technique for vitrifying substantial pieces of biological tissue. A reasonable consensus in the field accepts that a layer up to 200 μm (perhaps thicker) can be vitrified by this approach. High-pressure freezers are now available from three commercial companies and the application of this approach is growing slowly but steadily, worldwide in established EM laboratories. It should be emphasized that the technology involved is not trivial and there are many ''technical tricks'' that can be learned only from the specialists (this is generally true of all EM methods). Examples are shown in Figs. 13–15(b). Below, I would like to point out two very powerful adaptations that, in combination with high-pressure freezing, can be very powerful tools.

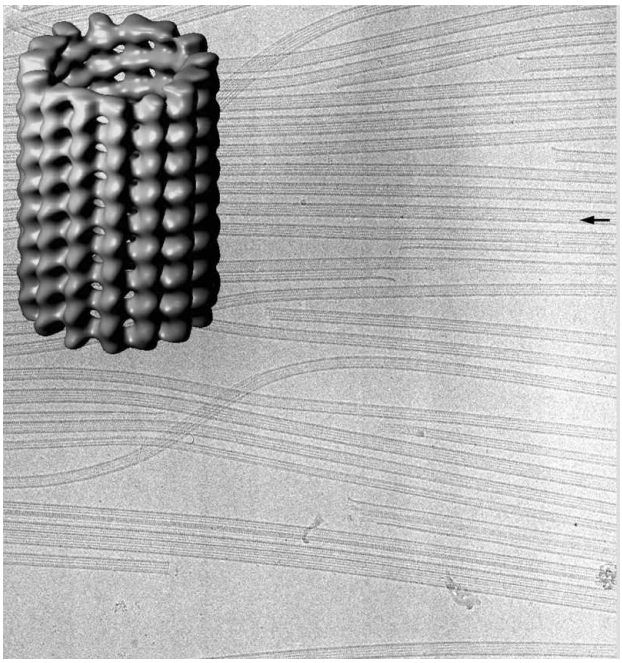
4.4 The Cellulose Capillary Tube

Hohenberg has introduced the use of cellulose microcapillary tubes in order

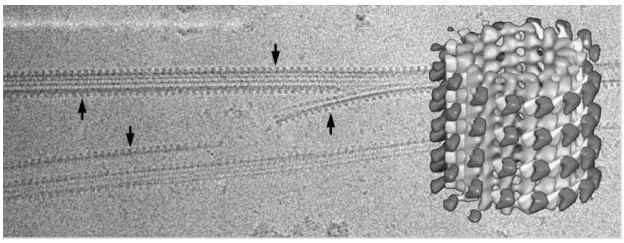
to prepare material for high-pressure freezing (HPF). By capillary action, an aqueous suspension can be drawn into these tubes of 200-µm diameter, which can be easily sealed by force. The cellulose wall allows molecules up to ~10 KDa to diffuse freely through it. Cultured cells can be grown within the tubes on their preferred media prior to freezing (see Fig. 13(a)). For high-pressure freezing, small fragments of these tubes can be conveniently positioned in the specimen holder of the machine. This approach can also be useful with other methods, for example, epoxy resin embedding or the Tokuyasu cryosection method.

4.5 The Fine-needle Biopsy

A second innovation by Hohenberg is potentially of enormous interest to pathologists. A specially designed jet micro-needle system has been developed that can cut



(a)



(b) Kinesin decoration

200-µm thick slices of any living tissue. These slices are ideal for high-pressure freezing. The use of this system for taking micro-biopsy specimens from human patients is now a routine (and for the patient apparently painless) procedure by this group and their medical collaborators.

4.6 Hydrated Cryosectioning

Vitrified thick specimens must be sectioned before analysis by TEM. The simplest method in theory, that is by far the most difficult to apply, is the hydrated cryosection method. The theory is indeed simple, one vitrifies a piece of tissue and prepares cryosections (at a temperature below the recrystallization temperature of vitreous water ($<-135\,^{\circ}C$)). These sections can be transferred onto EM-grids kept under liquid nitrogen until they are directly visualized (in the absence of any chemical) at $\sim-160\,^{\circ}C$, or below. In principle, this method allows direct visualization of native structure in the absence of any chemical.

In practice, the technique is quite demanding and is hampered by sectioning problems (cutting artifacts). Foremost among these is the severe compression (routinely 30–50%) that in fact accompanies all sectioning methods (in all other sectioning approaches for EM, the sections have the opportunity to stretch (decompress) on aqueous solutions). It seems, however, that in recent years all the major technical problems have found acceptable solutions and the method is now at the stage where it is ready to fulfil its promises. Moreover, new innovations are on the horizon, such as the vibrating diamond knife already mentioned that can considerably reduce the compression artifact and the use of tomography for providing three-dimensional information from such specimens. For recent examples of this approach, see Fig. 12.

4.7 Freeze-substitution

While the frozen-hydrated cryosection approach is currently something for a specialist, the approach of freeze-substitution offers a much easier-to-apply alternative method for visualizing the (close to) *in*

Fig. 11 Cryo-EM. (a) Cryoelectron micrograph of undecorated microtubules, embedded in vitrous ice. When assembled *in vitro*, microtubules may be formed from different numbers of protofilaments (which can be clearly seen in Fig. 22 after metal shadowing). A computer-assisted 3-D reconstruction in the inset (color) has been carried out on a 15-protofilament microtubule. One of them is marked with an arrow. The number of protofilaments gives rise to different moiree patterns, which can be seen on a careful inspection of the different tubes. For example, 13-protofilament microtubules exhibit very straight lines along the axis, while 15-protofilament microtubules show a characteristic alternating pattern of fuzzy and striated regions along the axis. This pattern allows one to identify different types of microtubules. (b) Cryomicrograph of microtubules decorated with kinesin motor domains; the corresponding model is shown. The motor domains appear as little globular blobs along the microtubule (arrows). These motor domains also have an intrinsic stabilization effect that creates long isolated protofilaments. The inset shows a helical 3-D reconstruction of a microtubule decorated with dimeric ncd domains. Ncd is a kinesin family member that exhibits retrograde directionality, and a unique microtubule-binding pattern, but otherwise shows strong structural similarities to conventional kinesin. It is important to realize that cryo-EM is the only approach that provides information about structural features *within* an intact particle. Images courtesy of Andy Hoenger. (See color plate p. xxiii).

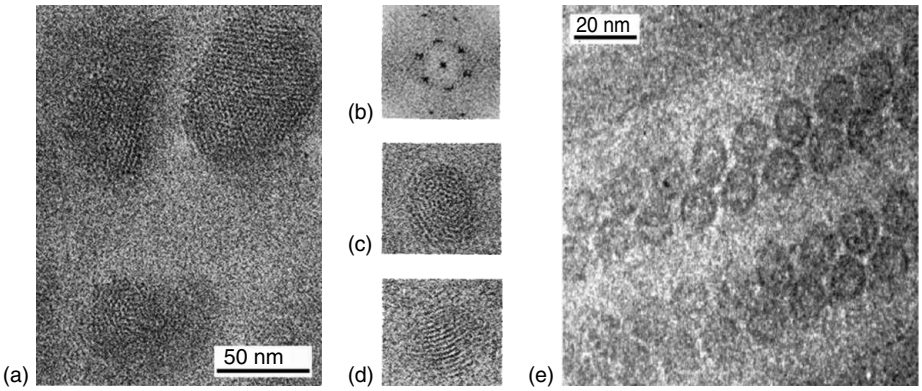


Fig. 12 Hydrated cryosections. In this approach, no chemical treatment whatsoever is used. (a) Shows a hydrated cryosection of stallion sperm chromatin after partial decondensation with 10 mM of the reducing agent DTT. The individual DNA filaments, whose diameter is 2.7 nm, can be clearly seen, as can their organization into a hexagonally arranged liquid crystal; (c) and (d) show different orientations of DNA; a diffractogram is evident in (b) showing the hexagonal spacing of the DNA. (e) Shows a hydrated cryosection through purified nucleosome cores that have self-organized *in vitro* into precisely aligned columns of particles. Both micrographs courtesy of Jacques Dubochet.

vivo structure. Although in this method the specimen is dehydrated and embedded in plastic, a comparison of the data from hydrated cryosections and freeze-substitution has nevertheless convinced most specialists that the latter approach offers many advantages over the former, except at the highest levels of resolution.

Freeze-substitution is an old EM method that went out of favor only to emerge over the past decade as the best routine method for preparing sections of faithfully preserved cellular material, thanks especially to the pioneering work by the groups of Müller and Steinbrecht. It can provide not only relatively high quality structural preservation but also the opportunity to label the sections (in contrast to hydrated cryosections) using immunogold methods.

The fact that *high-pressure freezing*, but no other approach, allows vitrification of up to hundreds of μm of depth in the specimen now makes this approach the method of choice for freeze-substitution.

The principle behind freeze-substitution is to infiltrate the vitrified specimen with solvents at low temperature that, over a period of many hours to days, gradually replace the water with the solvent (often mixed with stabilizing ''fixatives,'' such as OsO_4 (that cross-link lipids as the temperature is raised), or uranyl acetate (that can stabilize the head groups of phospholipids). The approach can also be carried out without any chemical fixatives. The idea here is to start the process of switching the specimen from a water-containing (vitreous) medium to a solvent that is compatible with the plastic embedding media at low temperatures (see below) while the structures of the biomolecules are still rigid. This is routinely done at, or colder than $-80\,^{\circ}C$. It cannot be ruled out that some cubic ice crystals may form under these conditions but even if they do they

are not noticeable at the levels of resolution usually desired.

In freeze-substitution, the tissue is either chemically fixed at low temperature and left to fix as the specimen is slowly warmed up, or left unfixed and embedded in specially developed methacrylate resins (such as Lowicryl HM23) at −70 to −90 °C, using UV polymerization. When labeling of antigens is not required, the specimen is warmed to room temperature, embedded in Epoxy resin, and then sectioned as in the conventional method. Figures 13 and 15 show images made using this approach. An alternative method that is not often used but may be appropriate for some specimens is to combine freeze-drying with freeze-substitution.

4.8 Freeze-fracture and Replica Methods

In the 1960s and early 1970s, freeze-fracture was a widely used approach, especially for the study of membranes. Although now restricted to a few specialist groups in the world, it is still the only method that can allow the investigator to see the insides of membranes. Small pieces of specimen are first vitrified, using a method such as slam-freezing against a cooled copper block or high-pressure freezing. Subsequently, the specimen is fractured, either with a knife, or by physically separating the frozen specimen that is sandwiched between two metal plates. The freshly opened surface is either evaporated with a metal replica directly, to reveal the surface details of the cut specimen, or the specimen is first allowed to warm up briefly to ∼−90 °C in order to etch away a layer of water. In this case, the replica also reveals some subsurface details; this is especially useful for visualizing details of the cytoskeleton, as evident in the pioneering studies of John Heuser, Tom Reese, Nobutaka Hirokawa and others. The underlying tissue is removed from the metal replica by harsh conditions such as immersion in chromic acid and the fine replica is attached to an EM grid and visualized by *ambient temperature* TEM. Thus, although this is a *bona fide* cryobased method, the replica of the frozen surface is finally visualized at room temperature.

A number of methods have been developed for combining freeze-fracture with immunolabeling. An especially interesting approach has already been developed by Kazushi Fujimoto; this method uses the detergent sodium dodecyl sulfate (SDS) to partially digest biological material from the replica while retaining integral membrane proteins whose exposed cytoplasmic domain are accessible for immunolabeling. Figure 16 shows two striking examples using this approach.

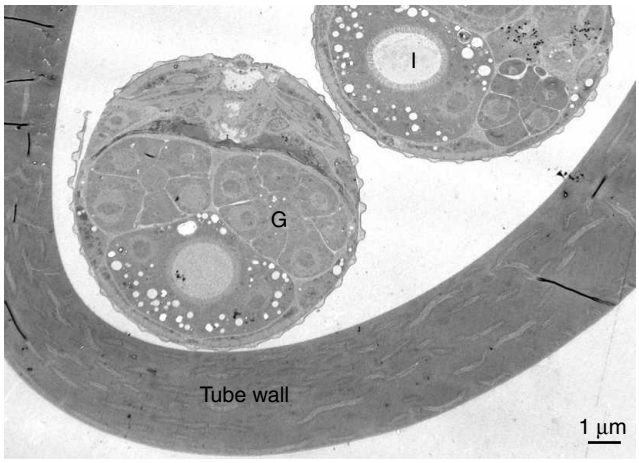
4.9 Simple Shadowing Methods

Since the dawn of the EM era, simple metal shadowing methods have proven useful as a substitute for negative staining that show particle surface structure. Any isolated particles, such as those suitable for the bare-grid cryo-EM negative-staining approaches can be usefully examined using this approach. When done well, the appearance of the structure can appear more three-dimensional than with negative staining. In the simplest instances robust structures can be air-dried before evaporating metal in a unidirectional, or rotary fashion. Better results are usually obtained after a more gentle preparation method, such as freeze-drying. Two examples are shown in Fig. 23. Another related method is glycerol spraying whereby the sample in glycerol is sprayed, then rotary shadowed and viewed

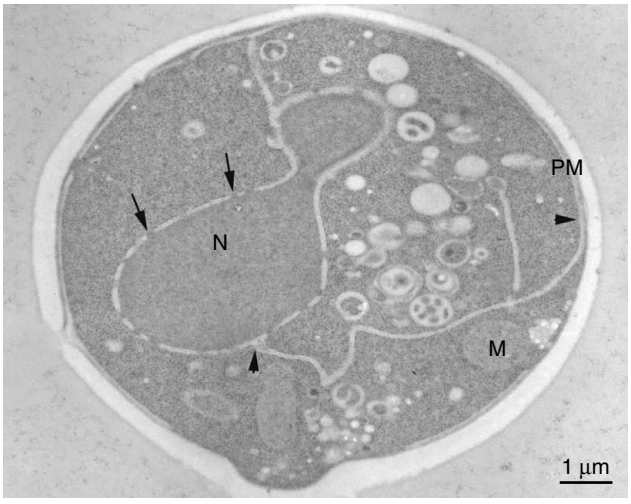
by TEM. This approach has been widely used to visualize isolated nucleic acids and attached complexes.

4.10 The Kleinschmidt and other EM Methods for Nucleic Acids

A useful method for visualizing DNA or RNA molecules, and attached complexes was developed by Kleinschmidt in 1959. The molecules are adsorbed to a thin, positively charged protein monolayer spread on a water surface. Cytochrome-C is the most commonly used spreading agent. The film is then picked up on a specimen grid, contrasted with stain (e.g. uranyl acetate) or by rotary shadowing with platinum, and observed in the microscope. This method may not have the resolution



(a)



(b)

of the cryo-EM method but is more suitable for estimating parameters such as the length of the fibers.

About 10 years after the introduction of the Kleinschmidt method, the heteroduplex analysis for mapping regions of base sequence homology in nucleic acids was established, particularly in combination with formamide as a denaturating agent. The use of a detergent film (BAC) to replace cytochrome-C later allowed a better resolution of the nucleic acid strands.

4.11 EM Autoradiography

Until the 1970s, the use of EM autoradiography had a central place in cell biological research. In this approach, a radioactive molecule is introduced into the cells/tissues as a ''pulse'' of signal; the classical example was the use of radioactive amino acids or sugars that are incorporated into newly synthesized proteins or glycoproteins. By removing the radioactive precursor, a period of ''chase'' allows the tracer to be followed sequentially in the cell. This approach was used to follow the ER to the Golgi pathway for secretory proteins and glycoproteins by the groups of Palade and Leblond in the 1960s. At the end of the experiment, the cells/tissues are chemically fixed and embedded in epoxy resins and sectioned. Subsequently, a thin film of radioactivity- (and light-) sensitive photographic emulsion is layered on the section surface under a red light source in the dark room. The sections must then be incubated for days, weeks, or even months for enough radioactive encounters to interact with the film. At the end of the incubation, the film is developed and visualized under the EM.

Although in principle an excellent method to follow defined molecules, a significant disadvantage is the relatively low resolution, at best 0.5 μm. This, plus the long waiting period, has resulted in its almost total disappearance from the cell biological scene during the past 20 years. Cell biological problems that used to be analyzed by autoradiography are now better resolved by use of specific antibodies; kinetic results can then be achieved by use of specific inhibitors, such as cycloheximide, that can help to synchronize the synthesis of proteins, for example, through the biosynthetic pathway.

5 EM-Visualization at Ambient Temperatures

All EMs are rather sophisticated machines because electrons can only be usefully

Fig. 13 High-pressure freezing and freeze-substitution. Shows freeze-substituted specimens following high-pressure freezing. (a) Shows the nematode *Diploscapter coronata* having been vitrified within a capillary tube (the tube wall is indicated); the freeze-substitution was done using osmium in acetone. I-intestine; G, gonad (b) Shows a section through a high-pressure frozen and freeze-substituted yeast cell (*Saccharomyces cerevisiae*). The specimen was embedded in Lowicryl HM20 resin. Yeast cells are notoriously difficult to preserve by conventional fixation methods due to their robust cell wall. This image shows remarkable preservation. The arrowheads indicate direct continuities between the nuclear envelope and the endoplasmic reticulum. This ER, seen in negative contrast, is continuous with a domain of ER that seems to be very closely attached to the plasma membrane (arrowhead adjacent to the plasma membrane (PM)). The nuclear pores are also evident in negative contrast (arrows). Mitochondria (M) and other organelles are also evident. Both images courtesy of Heinz Schwarz.

(b)

Fig. 14 Cryo-section immunolabeling of African trypanosomes. These figures show the trypanosome *Trypanasoma brucei*. (a) and (b) show Tokuyasu cryosections of this organism following labeling for the variable surface antigen (VSG). The VSG is seen to be heavily concentrated at the PM, the flagellar pocket (FP, the flagellum is indicated by F), throughout the Golgi complex (G), as well as in ER and endocytic organelles (not indicated). The arrow in (a) shows a labeled endocytic vesicle in the process of budding from the flagellar pocket membrane. Bars–300 nm. Courtesy: see Fig. 15.

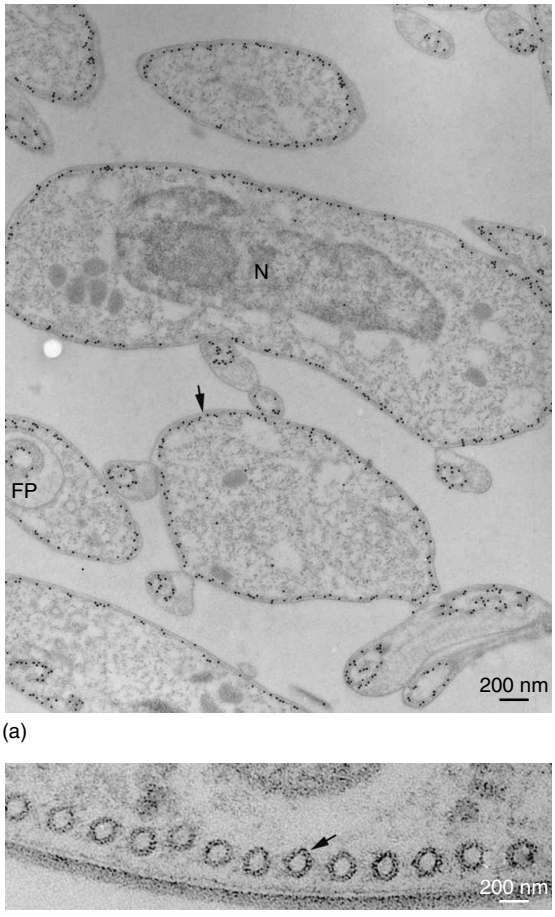

Fig. 15 Plastic-section immunolabeling of African trypanosomes. These figures show the trypanosome *Trypanasoma brucei*. (a) shows a trypanosome that was fixed in 0.05% glutaraldehyde/2% formaldehyde before being embedded in Lowicryl HM 20 after the progressive lowering of temperature method. The sections were labeled with anti-tubulin and donkey anti-mouse gold (12 nm). The array of microtubules beneath the plasma membrane and in the flagellum are strongly labeled (arrow). (b) Shows a trypanosome that was vitrified by high-pressure freezing followed by freeze-substitution in 0.5% osmium tetroxide, 0.5% gallic acid in acetone and room-temperature embedding in Epon. The excellent preservation of the microtubules is evident by the clear delineation of the tubulin protofilaments in cross-section. Micrographs courtesy of Christoph Grünfelder, Peter Overath, and Heinz Schwarz.

transmitted in a rather high vacuum (better than 10^{-3} Pa $\sim 10^{-4}/10^{-5}$ Torr). This high vacuum in the main column also needs to be maintained when a grid is introduced. For this, the grid is first introduced into a low volume prechamber (airlock) that is quickly pumped to vacuum. The grid can then be carefully inserted into the center of the objective (electromagnetic) lens. At the top of the microscope column is an electron source (tungsten filament, lanthanum hexaboride crystal) or, the (most coherent and expensive) field-emission filament. The specimen is observed at acceleration voltages ranging from 80 to 120 kV (standard) to 200 to 400 kV (new ''intermediate-voltage'' microscopes) or up to 1 million volts in the high-voltage EM (of which only a small number are available for biological research worldwide; the others have disappeared due to lack of interest). The recent developments in EM tomography will likely see a reversal of this trend, as methods to investigate thicker sections become more useful (see below).

The emitted electrons are attracted toward the anode leading to a coherent

(b)

Fig. 16 Freeze-fracture immunolabeling. (a) Shows chick liver, tight junctions labeled for the tight junction protein occludin while (b) indicates rat liver, gap junctions double-labeled for connexin 32 (large gold particles), and connexin 26 (small particle). The tissue slices were quick-frozen by contact with a copper block cooled with liquid helium. The frozen samples were fractured in a Balzers BAF 400 T freeze-etch unit at −110 °C, replicated by deposition of platinum/carbon (Pt/C) followed by carbon. After thawing and washing with PBS, the pieces of Pt/C replica were transferred to 2.5% SDS containing-buffer for 12 h at room temperature. Subsequently, the replicas were immunogold labeled, rinsed, fixed with glutaraldehyde, rinsed again, and picked up on grids. Micrographs courtesy of Kazushi Fujimoto.

beam of electrons that, with the help of an electromagnetic condenser lens, can then be converged onto the specimen. Electron-dense material (biological material heavy metal stains) scatter the electrons, whereas the electron-lucent parts of the specimen allow the electrons to pass down the column where, after magnification by the objective and projector lenses, they form an image on a phosphorescent screen, film or CCD camera. There are two different types of interactions between electrons and biological material; *elastically scattered electrons* interact with the specimen with a minimum loss of energy and therefore there is no change in the wavelength of the electrons. This type of scattering is due to a simple deviation of the electrons in the atoms in the specimen. In contrast, *inelastically scattered electrons* are those that experience energy loss and change of wavelength during their interactions with the electrons of the encountered atoms. These interactions give rise to the secondary events, such as heating the specimen, mass loss, contrast, X-ray emissions and cathodoluminescence.

When electrons interact with the phosphorescent screen, the green light emitted by fluorescence provides a signal that the human eye sees and the brain needs to interpret. By removing the phosphorescent screen transiently, the electrons can be directed toward photographic emulsion to record the image on film. Cooled CCD cameras are now rapidly replacing film but they are very expensive and still do not have the resolution available on film. It is likely to be only a matter of time before CCD cameras replace film completely.

The inelastically scattered electrons passing through the specimen can damage the specimen, resulting, for example, in *mass loss*, even in plastic sections. However, in practice, beam damage is not a serious problem for plastic or Tokuyasu cryosections, at the usual level of resolution needed. For vitrified, native specimens this is a very serious concern, as we will now discuss.

6 EM at Cold Temperatures

Imaging vitreous specimens, either bulk suspension, or hydrated cryosections, is a lot more difficult than imaging specimens at ambient temperatures. This is really not something that can be taught in a manual. Moreover, one has to deal with quite delicate and expensive equipment. A competent cryo-EM specialist needs to understand a lot about the physics of the processes involved. Native biological sections are extremely sensitive to the electron beam, and under the conditions used for ambient temperature specimens, they visibly boil away within seconds. This necessitates *low-dose imaging*. In the standard approach, the investigator can only surmise that suitable specimens are present at a site selected at low magnification, that is, immediately photographed at higher magnification using the minimum electron dose required for imaging. All focusing and image adjustments are therefore done at sites away from the selected areas. In recent times, the technology available with modern EMs has improved considerably, and is now much more user-friendly.

In most cases, the specimen is unstained and to acquire sufficient contrast to see the details is often a problem. For optimal images, one takes advantage of the increase in phase-contrast that is provided by underfocusing.

Nevertheless, the fact remains that more and more specialists are now routinely recording images of very high information

content with this technology. There is no doubt that at the top level the cryoimaging approach provides the highest resolution available in EM today (see Fig. 11). In suitable specimens, by averaging data from large numbers of micrographs, it can now approach (or reach) the atomic level of resolution (0.3–1 nm) when two-dimensional crystals are available. In many cases where a 1 to 3-nm resolution is obtained, the level of information often suffices to help one to fit higher resolution X-ray crystallographic data of the same structure into a comprehensive model of the structure. In this way, the details of the (high-resolution) X-ray structure are fitted onto its overall shape, which emerges from the (lower resolution) cryo-EM model.

It is important to realize that in order to "solve" a structure to the desired level of resolution, the availability of negatives or online images is merely the beginning of a long, complex, and often tortuous process. In contrast to ambient temperature specimens in which the images are mostly "final," in cryo-EM (as well as in some high-resolution negative stained specimen analysis), there is an increasing number of possibilities to obtain much more relevant structural information by use of computational *image processing* algorithms. The goal of these procedures is to improve signal-to-noise ratio by averaging a large number of structural units. The two main kinds of approach to obtain this goal are the following: (1) *Electron crystallography* (including helical reconstructions) of two-dimensional crystals and (2) *Single particle analysis*, including icosahedral particles, where particles imaged at various orientations are collected, averaged and superimposed into a three-dimensional model.

Examples of cryoimages obtained using sections are shown in Fig. 12 and from whole-mounts of particles in Fig. 11 and 19(a) and of cells in Fig. 19(b).

6.1 EM Tomography

In the past, if one wanted a three-dimensional view of a structure from thin sections it was necessary to use serial sections. The need to cut and maintain in perfect order up to a hundred or more thin sections is technically quite demanding and, until recently it was very difficult to subsequently align images from each section on top of each other in perfect register. In the past few years, a revolutionary alternative approach has started to have a major impact on EM at all levels. From either a single particle or a relatively thick section, *tomography* allows one to obtain a three-dimensional reconstruction of the structure of interest. In practice, a device for tilting the specimen, the goniometer stage, allows the grid to be tilted relative to the beam (under standard conditions + and $-\sim 70^\circ$; new goniometers are now reaching $\pm 80^\circ$). Images of all the projections are collected, usually at intervals of 1 to 2°. By "back-projecting" these images into a three-dimensional volume one can construct the original image in three dimension using now standard computational algorithms. The reader is also referred to a whole volume of the Journal of Structural Biology that was dedicated to the exciting developments in this field (Vol. 138, pp. 1–155, 2002).

There are a number of problems that can limit this approach. First, since there are a large number of images, the effects of beam damage have to be considered. In practice, this is not a serious problem for the "ambient temperature specimens" indicated above: one can take 130 to 140

images, 1° apart. However, for vitrified particles or sections, this problem is still a limitation; in practice one is currently restricted to, at most 100 images before the specimen is irreparably damaged. It should be emphasized that a great deal of effort has been made by a few specialists to make this technology available, with important developments in software, automatic image collection and in specimen preparation.

The second problem is the ''missing cone'' or wedge due to the practical limitation that one cannot tilt the grid ±90° – there will always be a part of the information that is missed, resulting in loss of resolution. For quasi-regular particles, one can overcome this problem by averaging a number of reconstructions from different viewpoints. For imaging complex structures in sections of cells, it may be possible to combine tomograms from sections that contain the specimen at different orientations.

In addition to being used in high-resolution EM for reconstructing single particles such as ribosomes this approach, in combination with high-pressure freezing and freeze-substitution, is now being applied to analyze the three-dimensional organization of different structures, such as whole yeast cells, the Golgi complex, mitochondria (see Fig. 18). Most of these studies have used relatively thick (−200 −300 nm) plastic sections. It should be noted that for the difficult question of deciding whether or not fine tubules connect certain structures (notably the Golgi complex), this approach can still leave open considerable room for subjectivity. In such cases, the use of heavy metal stains (e.g. the cytochemical reaction product of HRP, or other enzyme reaction products) to fill the lumen of tubules (e.g. by expressing HRP-containing constructs in cells) can greatly aid the analysis.

The ability to visualize *whole cells* directly by a transmission cryo-EM approach can be considered the ultimate goal in electron microscopy. It is now fascinating to consider that, prior to the development of robust methods for preparing thin resin sections of cells, the famous trio of Porter, Claude, and Fullam had made initial attempts in 1945 to visualize cells grown on EM-grids (after osmium tetroxide vapor or formaldehyde primary fixation). Despite the harshness of the preparation (by today's standards), what was observed was striking. In the thinner, peripheral regions of the fibroblast, whose outlines are clearly delineated, one can clearly see mitochondria, filaments and so on (see Fig. 17).

In an important development, the Baumeister group have succeeded in bringing together a whole battery of technical developments to enable the experiment to be redone with state of cryo-EM tomography. In their first publication, they focused on the amoeba, *Dictyostelium,* that in accompanying videos could be seen to move rapidly across the grid just before vitrification. Although one has to accept the (still significant) limitation that only cell projections thinner than ~400 to 500 nm could be clearly analyzed, the details shown are amazing, at a resolution of ~5 nm. It must be realized that this is the first time it has been possible to look directly inside a relatively unperturbed cell at this level of resolution. An example is given in Fig. 19(b).

With more developments, and more widespread use of this approach, (likely aided by higher accelerating voltages and energy filtering) thicker regions of the cell will become more accessible for analysis. The use of hydrated cryosections

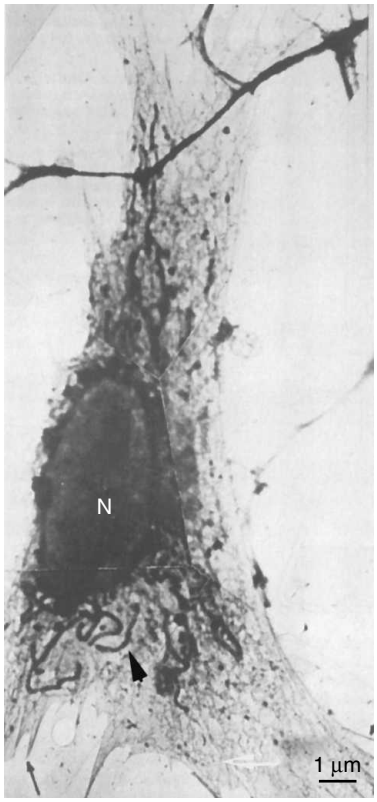

Fig. 17 One of the first micrographs of cells. Shows a famous micrograph taken from the paper by Porter, Claude, and Fullam from the Journal of Experimental Medicine (1945). This micrograph is one of the first ever taken by electron microscopy. The cells were grown on an EM grid, fixed in osmium tetroxide, air-dried, and visualized as a whole mount. Micro spikes (arrow) at the leading edge are evident, as is the nucleus and the worm-shaped mitochondria. A fine reticulum beneath the mitochondria is likely to be the endoplasmic reticulum. This image has already been shown in a wonderful book by Christian de Duve in 1984.

can be expected to complement these efforts. The ability to reconstruct detailed structures (e.g. within the nucleus) will greatly increase the level of information one can obtain from these preparations. Tomography can also greatly simplify the interpretation of the three-dimensional structure from hydrated cryosections.

6.2 Low- and High-resolution SEM

The ability to visualize surface structures by scanning EM is well known, even to many nonscientists, a result of spectacular images of animals, plants, and microorganisms obtained by this approach. Many specimens, such as insects have robust exoskeletons that can withstand beam damage and only a thin layer of metal needs to be evaporated before visualization; for a beautiful example see Fig. 20. This low-resolution SEM approach method is widely used. At a higher level of resolution, parts of the organ of Corti of the ear are seen in Fig. 21.

Over the past 20 years, the use of higher resolution SEM in molecular cell biology has dwindled – only a handful of laboratories currently use this approach. This is indeed surprising, and very disappointing given the proven ability of this approach to see high-resolution details of structures such as nuclear pores, bacteriophages (Fig. 22(a, b)) and actin filaments (Fig. 22c).

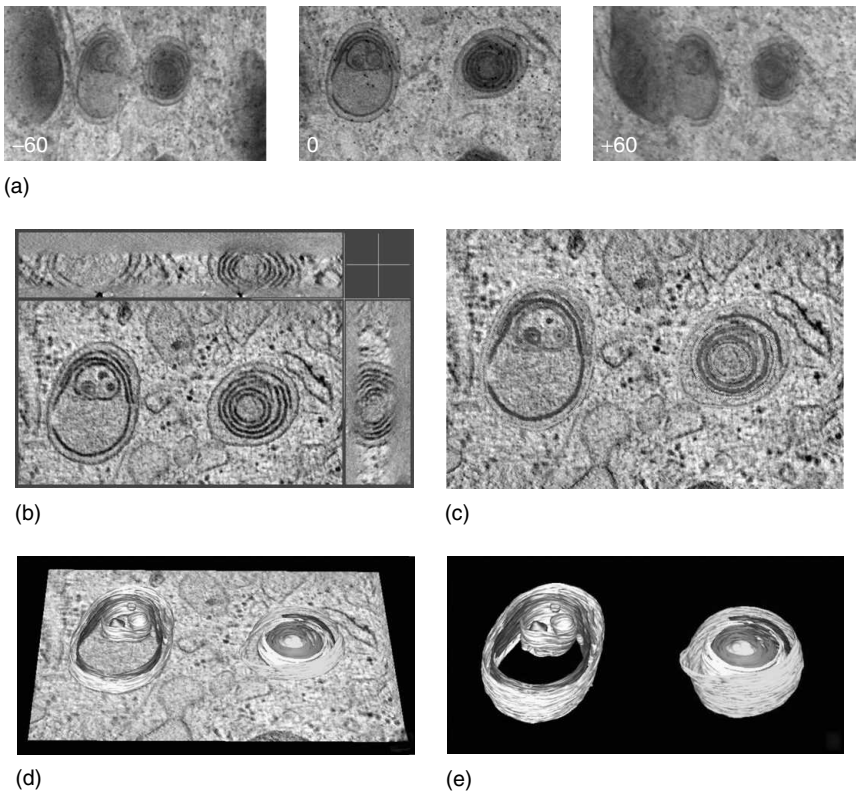

Fig. 18 EM Tomography from plastic thick sections. (a) To obtain a three-dimensional reconstruction of an organelle, a tilted-series of images is recorded. A 250-nm section of multilamellar lysosomes in a mouse dendritic cell is shown after high-pressure freezing, freeze-substitution, and resin embedding. This, relatively thick section was tilted from −60° to 60° along two perpendicular axes to produce a tilt-series of 242 images. This panel shows three of these images, collected at −60, 0, and 60° tilting. The small black dots in the images are 10-nm gold beads on top of the section, which are used as fiducial markers (reference structures) for the three-dimensional reconstruction. (b) After calculating the three-dimensional reconstruction from the tilt-series, the three-dimensional volume can be analyzed by displaying it as thin, so-called tomographic slices. The slices can be made along every possible axis. Three slices through the tomographic volume are shown: top: X-Z, middle: X-Y and right: Y-Z. (c) By manually tracing the membranes of the multilamellar lysosomes in the tomographic volume a three-dimensional model is created. (d) Shows a three-dimensional model top view of one of the tomographic slices, while (e) reveals the three-dimensional model view of the endocytic vesicle. The figure was provided by Jean-Luc Murk and Bruno Humbel. From a study by Murk et al., J. Microsc. in press.

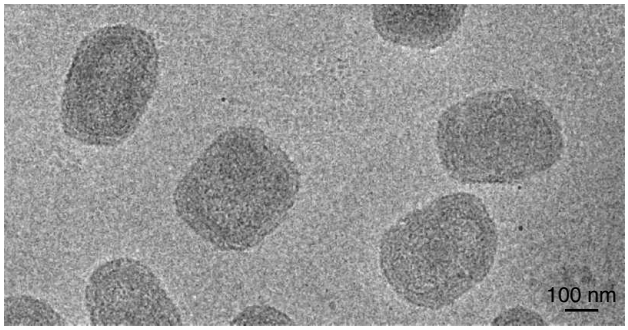
In conjunction with immunogold labeling prior to vitrification, the use of cryo-SEM, especially the remarkable new generation of field-emission (FE) scanning electron microscopes offers the molecular cell biologist a complementary approach to tomography. SEM visualizes the surface of the structure directly in three dimension. In conjunction with the pioneering efforts of a few specialist groups (especially those

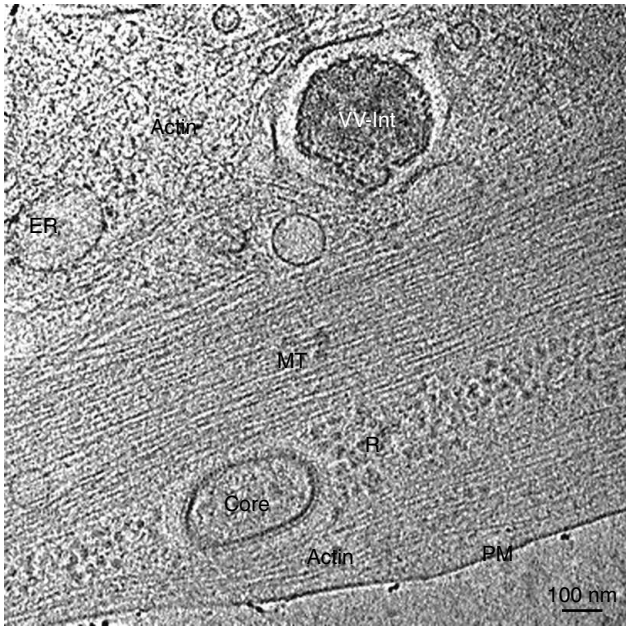
of Martin Müller, Paul Walther, Hans Ris and Terry Allen) in developing new approaches for specimen preparation, this method is now capable of extremely high-resolution (1–3 nm) (Fig. 22). A number of publications have shown the great potential of this approach, also for immunogold labeling, especially when gold particles as small as 1 nm are used, that can be visualized in the backscatter mode. In some studies, Fab domains have been used instead of whole IgG molecules to increase the precision of the labeling.

6.3 Critical Point Drying

The most common method to prepare living specimens for SEM has been chemical fixation followed by critical point



(a)



(b)

Fig. 20 Classical SEM. Shows a beautiful image of *Drosophila melanogaster* visualized by conventional SEM. The insect was fixed with glutaraldehyde, rinsed, critically – point-dried and sputter coated using gold-palladium. Fine details of the surface of the insect can be seen in artistic detail. Micrograph courtesy of Jürgen Berger (Max Planck Institute for Developmental Biology, Tuebingen, Germany).

drying (CPD). The basic idea of this approach is to prevent drying artifacts, which occurs when the sample is exposed to the surface tension of the liquid–gaseous phase border. This method has also been extensively used for preparing material for TEM replicas and for epoxy resin embedding. For this, the specimen is chemically fixed and dehydrated in solvents such as ethanol (essentially as for epoxy resin embedding). Later the solvent is replaced by liquid carbon dioxide in the pressure chamber of the critical point drying device. Then, the carbon dioxide is slowly warmed up. This causes the pressure to rise in the closed system. When the temperature and pressure pass above the so-called *''critical point''* of carbon dioxide (31 °C and 74 bar), the pressure is carefully reduced and the sample removed once room pressure is reached. The specimen is thus dried without ever having seen the liquid–gas phase border, which can cause major distortions to a sensitive specimen. Recent applications of the CPD method in cell biology are the preparation of cytoskeleton elements after detergent treatment and TEM replica. As pointed out by Ris, it is very important to remove every trace of water from the specimen before the next stage, which

Fig. 19 Cryo-EM and tomography. (a) Shows cryo-EM of vitrified vaccinia virus using the bare-grid method. This virus is enormously complex as was already evident in Fig 4. Although a tremendous amount of information is present in these particles, at present the detailed three–dimensional organization of the virus remains to be deciphered and the tomographic approach is now in progress. (b) Shows the 2002 equivalent of the experiment already carried out. Hela cells were grown on EM-grids and vaccinia virus was added. The goal of this experiment was to visualize intermediates in the entry of the virus into the cell, a highly complex and not understood process. The grid was vitrified and examined by cryo-EM. This image is a section through a tomogram (not a physical section) showing details that are not approachable by single projections. The upper particle is, we believe, an intermediate (from VV-Int) in the entry of the viral core and is likely to be still outside the cell. In contrast, the viral core, which is transcriptionally competent, having lost its outer membranes is definitely within the cytoplasm. Actin filaments are seen in the lower part of the micrograph, whereas the filaments above the core are microtubules. Ribosomes (R) are also evident, as is the ER. This method is the first approach available for looking inside physically and chemically unperturbed cells by EM at this level of resolution. Bars = 100 nm. Both micrographs courtesy of Marek Cyrklaff; specimen provided by Jacomine Krijnse Locker.

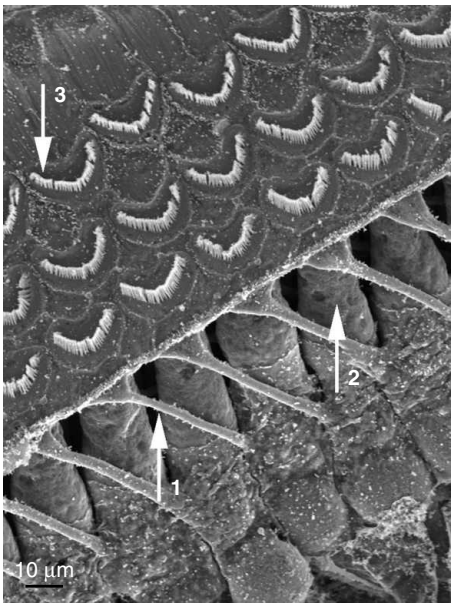


Fig. 21 SEM of the organ of Corti of the mouse ear. These SEM images show a guinea pig cochlea dissected to remove Hensen cells (sensory cells of the ear and the supporting cells). Hensen cells were dissected to give a clear view of the outer hair cells, the sensory cells of the ear (2) and supporting cells. The tops of the outer hair cells have stereocilia attached (3) the chevron-shaped projections) and the main body of the outer hair cell can be seen below. (1) indicates the outer phalangeal cells of Deiter. The specimen was fixed in glutaraldehyde before dissection and then infiltrated with tannic acid and osmium tetroxide. This facilitated examination without metal coating in a field-emission SEM (a Philips XL-30 FESEM operating at 5 kV). This specimen preparation method was a modification of the method of Jongebloed et al. (1999). Micrograph courtesy of Paul Webster.

for SEM involves coating the specimen with a thin layer of metal (see Fig. 23).

6.4 Freeze-drying and Cryo-SEM

The SEM is able to image the physical surface only. In most biological samples, however, the structures of interest are inside cells and tissue. To get access to the structures of interest, the specimen has to be opened by cracking or by sectioning, or the overlaying water must be removed. This is only possible with a solid-state sample. The most straightforward way to solidify a biological sample is by vitrification. In the cryo-SEM, bulk samples can be investigated over a very large range of magnification, from the resolution level of a dissection microscope up to macromolecular resolution. After being immobilized, by cryofixation the samples can be investigated in the cryo-SEM in the fully frozen-hydrated or in the partially freeze-dried (''deep-etched'') state. Many artifacts of conventional chemical fixation and dehydration techniques can, thereby, be prevented.

Removal of the vitrified water is possible by sublimation in the vacuum in the microscope or in a preparation chamber. This preparation step is also called ''*freeze-etching*'' with a partial sublimation of the water, or freeze-drying in the cryo-EM literature. When the water is partially removed, the three-dimensional arrangement of the structures in the cytosol can be investigated. Current methodological research focuses on a better control of the ice-sublimation process.

This method also has a high, and still not fully used potential for the analysis of *in vitro* systems in cell biology. Together with Paul Walther, our group is currently investigating actin-membrane interactions using these cryo-SEM approaches.

(c)

6.5 Coating Techniques for Cryo-SEM

Samples for high-resolution SEM are usually coated with a thin metal layer in order to enhance electrical conductivity and to localize the signal on the surface of the sample. Charging of the sample can also be reduced by working at low accelerating voltage of the primary beam (e.g. 2 kV). It was, however, pointed out, that the excitation volume of the secondary electrons is increased when they interact with an insulator. Therefore, it is advantageous to work with coated (shadowed), conductive samples, even when working at low voltages. Relatively thin samples can ideally be supported by a uniform layer of an electrically conductive material, for example, by 1 nm of tungsten. Bulk cryofractured samples, however, are insulators and very beam-sensitive. For these samples, double layer coating has been very useful. The sample is first coated with a contrast-forming layer of heavy metal (platinum or tungsten), both to enhance electrical conductivity and for mechanical stabilization. A carbon layer with a thickness of 5 to 10 nm is then applied on top of the platinum layer. As shown in different studies, this layer drastically reduces the effects of beam damage. For the analysis of these samples, the backscattered electron signal has to be used, which is mainly produced by the metal coat that stays in direct contact with the biological structure of interest.

6.6 Scanning Transmission EM

A specialized variation of transmission EM is scanning transmission electron microscopy (STEM, done mostly in the dark-field mode) in which the specimen on the grid is scanned in a raster pattern with a finely focused electron beam. This offers precise determination of the absolute mass of the specimen irrespective of shape.

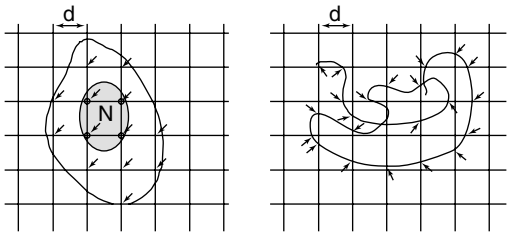
6.7 X ray Elemental Microanalysis by EM

X-ray microanalysis of biological specimens can be conducted at two different levels of resolution. Low-resolution microanalysis is typically performed using a scanning electron microscope equipped

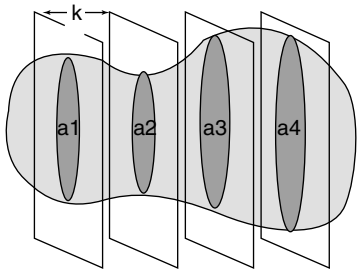
Fig. 23 Metal shadowing for EM. (a) Shows the identical TMV particles that were seen by negative staining in Fig. 3. This unpublished image, over 30 years old, was unidirectionally shadowed with platinum. (b) Unidirectional surface shadowing (tantalum/tungsten, elevation angle -45°) of a microtubule stabilized with small amounts of tau-protein. This protein is essentially invisible due to its highly filamentous structure. This leaves a surface pattern typical for microtubules, exhibiting the outer protofilament surface as a continuous axially oriented rim. The arrow shows a protofilament splayed out at the end of the microtubule. (c) Unidirectional surface shadowing of tubulin that coassembled with walls of monomeric kinesin molecules *in vitro*. The presence of these molecules renders the outer surface in a completely different way relative to the undecorated microtubules in (b). Instead of an axial striation, one now observes a perpendicular striation with an axial 8-nm repeat (arrows), which corresponds to one motor domain bound to each α, β-tubulin dimer. This method allows one to clearly distinguish between inner and outer microtubule surface. The inner surface exhibits a 4-nm repeating pattern according to each tubulin monomer. (a) Courtesy of Herman Frank and Heinz Schwarz; (b) and (c) courtesy of Andy Hoenger.

with an X-ray detector. This application is typically used to analyze small particulate inclusions in cells and tissues. The analysis of environmental heavy metal contamination, foreign body ingestion, and occupational exposure are the most typical applications. Examination of cells and tissues in the scanning electron microscope using the backscatter electron imaging mode can also be used to provide low-resolution information, for example, inclusions and particles containing high atomic number atoms can be identified in association with particular cell types.

X-ray microanalysis of biological specimens can also utilize a transmission electron microscope coupled with an X-ray detector, but the demands of specimen preparation and specimen handling are much more challenging. Typically, this high-resolution technique requires the rapid freezing of small, undamaged biological specimens. The biological specimen requirement involves selecting small (less than 1 mm) specimens, which must be solidified using ultra rapid freezing techniques leading to vitrification. Subsequently, the small specimens are mounted in a cryoultramicrotome using either mechanical clamping or a low temperature cryoglue. The ultrathin sections with thicknesses of about 100 to 120 nm are prepared and transferred to formvar-coated double-folding (sandwich) grids in the cryochamber of the cryoultramicrotome. The grid is next transferred to a cryotransfer stage at $-170\,^{\circ}C$. The cryotransfer stage is inserted into the transmission electron microscope. The transmission electron microscope must be equipped with a liquid nitrogen cooled anticontamination device to prevent the deposition of water vapor onto the specimen from the column of the electron microscope.



(a) Point counting (b) Intercept counting



Position of the first plane uniform random in [0,k], estimate of volume = $k(a_1 + a_2 + a_3 + a_4)$

(c)

For X-ray microanalysis, the specimen must be warmed to about −100 °C, which allows the water in the specimen to sublime onto the anti contaminator. This freeze-drying step generally requires 45 to 60 min to achieve a specimen that will withstand the high-beam currents necessary for high-resolution X-ray microanalysis. Using this technique allows the analysis of subcellular regions in individual cells such as mitochondria, lysosomes, cytoplasm regions, and nuclear regions.

The critical assumptions in this technique are (1) the freezing process does not translocate diffusible elements from their native location; (2) that the cryosectioning process and freeze-drying of the ultrathin section in the electron microscope also do not translocate diffusible elements from their native sites, and (3) that during analysis under the high electron beam current the diffusible elements also remained in their native location. In practice, these criteria are rarely fulfilled for small, mobile ions of cell biological interest, such as calcium or magnesium. In general, these technical difficulties have limited the applications of this technique in cell biology.

An additional limitation is the lack of sensitivity to small changes in concentrations of sodium, chlorine, potassium, and calcium in the small subregions of cells. Under optimal conditions using freeze-dried thin sections, the limit of detection for X-ray analysis in general is about 100 parts per million. It is very difficult to estimate the water content of the subcellular regions so that the dry weight concentration measurement can be converted to a wet weight concentration that is meaningful to biologists.

Fig. 24 Principles of Stereology. (a) Shows the principle of estimating area using point counts. A transparent lattice grid is randomly positioned over the images of a structure, in this case, a hypothetical profile through a cell, the nucleus N is shown. The point where the edges of the two lines of the lattice meet each other is considered to be a unique point (arrows). One simply counts the number of points over the structure of interest. In this particular example, there are 13 points in total over the cell, four of which follow the nucleus. If this result were seen after averaging over a number of micrographs, this means that the nucleus represents 4/13 = 30.7% of the cell volume. The number of points $P \times d^2$ provides an estimate of the area of each structure on the micrographs. (b) Shows the principle of intercept counting to estimate the boundary length of surface. In this example, a square lattice grid with random orientation and position is placed over a piece of string. The arrows indicate the positions at which the lines of the string transect the lines of the grid: These positions (formally defined by the intersection of the edges of the line and one edge of the string) are referred to as intercepts. The length of the line is then given by $\pi/4 \times I \times d$ where I is the number of intercepts and d is the distance between the lines of the lattice grid. This principle, first introduced by Buffon, is an unbiased estimator of the length of the profile, and can be converted to surface area in three dimensions. In this example, if $d = 1$ cm and there are 21 intercepts, then the length of the string is $\pi(3.142)/4 \times 21(\text{Intercepts}) \times 1\text{ cm} = 16.495$ cm. (c) Shows the principle of the Cavalieri method. The principle here is to section a three-dimensional object with a series of equally spaced sections such that the position of the first section is random within the interval between the sections. In this example, four sections are made, a1–a4, and the volume is then given by the sum of the areas of the object displayed on the sections multiplied by the distance (k) between the sections (section thickness). This method is justifiably considered to be a powerful method for stereology, and has been widely used for many different organs, tissues, cells, and organelles. Diagrams courtesy of John Lucocq.

Theoretically, the water content could be estimated by making measurements before and after freeze-drying; however, fully hydrated specimens in the electron microscope are intolerant of the high-beam currents that are necessary for X-ray microanalysis.

In summary, the most useful methods involving X-ray microanalysis at present are performed in the scanning electron microscope at low resolution for studying occupational exposure, mineralized tissue, and calcification associated with disease processes.

6.8
Energy-filtering Transmission Electron Microscopy (EFTEM)

This approach allows improved imaging of thick sections and frozen-hydrated specimens by removing inelastically scattered electrons. The amount of inelastic scattering increases with specimen thickness (in general quite rapidly) and is dependent on the incident electron energy and on the material the beam is interacting with (in general, the heavier the material, the stronger the interaction). In EFTEM, the electrons are separated according to their energies, making it possible to filter out the blurring effects seen with thick sections, as well as retrieve selected chemical or physical information from the specimen. This additional electron selection results in contrast enhancement for all imaging modes and also provides the possibility of selecting electrons with specific scattering effects for imaging, thereby generating object- or element-specific contrast. For more details as provided by one of the manufacturers of this technology, see (www.leo-em.co.uk/temproducts/principle.htm).

7
Stereology

Although many cell biologists have yet to realize it, a remarkable set of methods has been developed over the past 30 years for quantifying the sizes, contents, and spatial relationships of biological structures. These methods are known as *Stereology*, a rigorous, probability-based discipline for estimating three-dimensional structural quantities (including volume, surface area, length, and number) and spatial relationships from sectional or slice images. The methods are design-based, meaning that they rely on the principle of random sampling (especially systematic random sampling) and offer the twin benefits of no (or minimal) bias combined with high precision. The work needed to implement them is, surprisingly, less than generally expected, so these methods tend also to be highly efficient. The use of stereological methods will be outlined, as will recently developed approaches for quantifying immunogold particles that are used to detect specific antigens.

The *sine qua non* of stereology is the application of geometrical probes for estimating two-dimensional and three-dimensional quantities. Crucial for this goal is unbiased sampling at all levels of specimen preparation and imaging: each specimen (e.g. an organ), and each part of that specimen (e.g. its different tissue compartments), must have an equal chance of being sampled. For some quantities, it is necessary to randomize the orientation of sectioning as well as section position. A number of books and chapters cover these important aspects in great detail. In order to give the flavor of how stereology works, we shall consider one method available for determining the absolute volume of any structure and

two standard methods for determining relative surface area (or length of sectional membrane image) and relative volume (or profile area of sectioned structures). It will be seen that, once the absolute volume of a reference structure (e.g. the nucleus or the cell) is known, it is possible to calculate the absolute total surface and volume of any compartment in the cell using their estimated relative surfaces and volumes. It is equally easy to obtain higher-level quantitative information about cells in tissues, organs, or whole organisms.

7.1 Relative Area and Volume

In order to estimate the areas of the sectional images (profiles) of different structures on micrographs, transparent plastic sheets having a uniform array of ''test points'' are randomly superimposed over the image (see Fig. 24(a)). The positioning of the overlay with respect to the specimen must be randomized. These days, this can also be conveniently done by computer. Since each point corresponds to a precise area, the total sectional area of any structure is then directly proportional to the average number of points falling over it. For a set of micrographs, the test points are summed and averaged; relative areas can be equated with relative volumes. The relative numbers of test points falling on different structures within the specimen then provide unbiased estimates of the relative profile areas of these structures.

The relative point totals (and relative areas) may be converted into relative volumes (volume densities, volume fractions, or volume proportions) using the principle first described by the geologist, Delesse, in 1848. If the micrographic images themselves represent a set obtained from randomly positioned sites throughout the specimen, the relative number of test points on each structure is not only an estimator of their relative profile areas but also an estimator of their relative volume in the specimen (in fact, the points then sample three-dimensional space). This simple and efficient point-counting approach therefore allows the possibility to characterize a set of cells in terms of their relative contents of nucleus, cytosol, mitochondria, Golgi complex, and any other compartments of interest.

7.2 Relative Profile Length and Surface Area

There is a simple but precise method for estimating the length of a linear trace (line on a sectional image), irrespective of its shape or orientation. On the basis of the principle first observed by Buffon in the nineteenth century, a system of parallel test lines is randomly laid over the profiles of interest. The lines must be randomized in terms of both their position and orientation. This principle can be simply illustrated with a piece of string, which is crumpled (so as to randomize its orientation) and then laid flat on a system of test lines (Fig. 24(b)). The number of times the string is intersected by the test lines (separated by distance, d) is counted and provides a simple and unbiased estimation of the length of string. If the lines on the overlay run in both ''horizontal'' and ''vertical'' directions, the length of the string is estimated by the formula $\pi/4 \times I \times d$, where I is the number of intersections and d is the distance between the lines of the grid (Fig. 24(b)). It is easy to visualize the linear traces of membranes on TEM thin sections as the equivalents of pieces of string.

By an analogous three-dimensional approach based on randomly oriented encounters between section planes and cell or organelle membranes, the relative number of intersections between test lines and different membrane compartments allows one to estimate their relative surface areas, that is, surface of membrane per volume of reference space. This simple and efficient intersection counting approach therefore allows the possibility to characterize cells in terms of the surface areas of their different membranes.

7.3 Absolute Volume

Sometimes it is not possible to estimate volume by, say, Archimedes principle of liquid displacement or by weighing, and it is necessary to resort to sectioning. An elegant method for estimating the volume of any structure by sectioning it was invented by Cavalieri in the seventeenth century. It was somehow forgotten until it was rediscovered by Gundersen and was given more general applicability as a stereological principle. The essence of the method is simple. First, the structure is sectioned completely into a uniform random set of slices (Fig. 24(c)). One can analyze each section but, as already mentioned, a great strength of stereology is the concept of sampling. One systematically selects a subset of (e.g. 1 in every 5) sections. On each sampled section, the area is estimated by, say, the test point–counting procedure. The combined area of all the sampled sections is then multiplied by the mean distance between selected sections to obtain the Cavalieri estimate of volume. When proper sampling procedures are followed, this is a remarkably efficient and precise estimator of volume, at scales ranging from a lysosome to a human brain. It can produce volume estimates with a precision of 5%, or less, from just 5 to 6 sections chosen in a systematic random fashion.

7.4 Surfaces and Volumes in Practice

Using the above principles for estimating relative surfaces and volumes, it is easy to appreciate how one could estimate the absolute surface or volume of any cell structure that is larger than the average section thickness (for technical reasons smaller structures are problematical by these methods). For this, one needs to know one quantity in absolute terms. For most cells, biological questions that refer to quantity would pertain to the average volume of the cell (or its nucleus). The *Cavalieri principle* can be used to estimate cell or nuclear volume by either LM or EM. A rather simple method is to stain cell nuclei with a DNA dye, such as Hoechst dye or Dapi. By confocal microscopy, one can optimally section through a set of nuclei and, knowing the distance between sections (given by differences in the focusing plane) and the areas of sections (as above), one can estimate the average nuclear volume by the Cavalieri principle. It is also possible to use 0.5 to 1 μm (semi-thin) section by EM (most nuclei in cells are 10 μm or less in diameter so a relatively small number of sections suffice). At 0.3 μm (or less), the procedure can be done by EM.

Knowing the absolute volume of the nucleus, one would next take random sections at the EM level. For volume estimation, only the position of the sections relative to the specimen needs to be randomized but, for surface estimation, both the position and orientation of the sections must be randomized. At a fairly

low magnification, the overlay of test points can be used to tell us the relative volume of the nucleus to the whole cell. For example, if on average 40 points hit the nuclear profiles and 160 points hit the cytoplasm, the nucleus occupies 40/200 or 20% of the cell volume. If the nuclear volume is known (from above), the absolute volume of the cell is five times that of the nucleus.

The volume of any subcellular compartment of interest can now be estimated by multiplying its volume ratio in the cell (V_V) by total cell volume. Similarly, any surface of interest can be estimated by relating the number of intersections hitting the (membrane) profile of the compartment to the number of points that fall on the entire cell. This gives us the ratio of surface of that membrane to the volume of the cell (S_V). Since $S = S_V \times$ cell volume, this gives an indirect but precise estimate of the absolute surface of the compartment.

There are also ingenious methods (again from Gundersen) for estimating particle *numerical density* (number in a reference volume) or total particle number. Numerical density is estimated by the dissector method, which relies on analysis using two consecutive sections and an unbiased counting frame. If the reference volume is known, an indirect estimate of number is obtained by multiplying this reference volume by particle numerical density. However, number can sometimes be estimated directly using the *fractionator* method. These two approaches have revolutionized the ability of investigators to provide unbiased estimates of the numbers of cells in different tissues, most prominently in various parts of the brain.

Using the test point and intersection counting principles described above, simple methods are available for quantifying immunogold labeling. A major advantage of the most recent developments is the ability to compare observed distributions of gold particles with predicted distributions obtained by counting test points (organelle compartments) or test-line intersections (membrane compartments). The idea here is to use the uniform distribution of the points and intercepts as indicators of randomness. Their predicted distributions correspond to the patterns expected for random labeling. Comparing observed and predicted distributions allows one to identify compartments that are preferentially labeled and to obtain estimates of their labeling densities and relative labeling indices.

A number of stereology courses are offered regularly in Europe and in the United States and the interested reader is well advised to attend such a course. Stereology is not only a set of methods; it offers a completely rigorous way of thinking about good study design in cell and tissue biology. For quantifying structural parameters or for immunolabeling, the use of stereology should be standard. What is most surprising (given the relative lack of its application for cell biology) is that the stereological approach can be so rapidly and efficiently applied.

7.5 Correlative Light and Electron Microscopy

It is not widely appreciated that sections cut for immunolabeling at the EM level can also be very useful tools for labeling at the LM level. This is true for plastic sections such as Lowicryl and for Tokuyasu-thawed cryosections. Since the labeling is restricted to one thin layer on the section surface, this approach can provide better resolution than confocal microscopy. Moreover, multiple fluorescence labeling with different antibodies on

different successive serial sections is possible; since each section (or small number of consecutive sections) is labeled independently there is no restriction on the combinations of antibodies used, for example, three different mouse antibodies can be used, each identified using a different, distinguishable fluorochrome. DNA stains such as Dapi are also very useful since they can be used to find the thin sections by light microscopy. Since the sections are thin, a series of sections covers the same structures and the images from the different antibodies can usually be combined to give pseudo-multiple labeling.

Recently, an elegant method has been developed that allows visualization of GFP-labeled structures in a living cell and then allows to identify the same cell (using an HRP-based approach) at the EM level.

7.6 Interpretation in EM

Seeing and understanding something in three dimension is infinitely easier than trying to interpret two-dimensional (section) images. Thin sections of cells are highly deceptive because they may seduce the investigator into thinking that the inside of the cell is open to a three-dimensional interpretation. In principle, it is, but the fact remains that it takes many years of looking down the microscope before one can be considered a professional. The loss of the third dimension is a more serious problem than is often imagined.

An example was provided of a well known and highly accomplished electron microscopist, who misinterpreted the early thin section images of the ER-cisternae as a system of parallel fibers. This example is useful because a large number of (even experienced) cell biologists automatically think they see a thin ''tube'' (in 3D) when they visualize profiles of cisternae (especially when the profiles are relatively small).

Another significant challenge facing the beginner in interpreting thin sections is how to average information over many cell profiles, no two of which can be considered really identical! Biases are rampant in the field as one or a few ''representative'' micrographs are selected for publication. This is especially a problem in presenting immunolabeling images in the absence of quantitation.

7.7 Which Technique for Which Question?

Faced with all of these different possibilities for preparing specimens for EM, the beginner may have difficulty deciding where to start. The first advice is to contact a specialist laboratory. Much will then depend on the scale, whether the starting specimen is isolated vesicles, cells, tissues, or an organism, whose size can scale from a virus or bacterium to a whole organism, such as an insect. Starting at the highest scale, the surface of an organism less than about 1 mm can be visualized directly by SEM. Above this size, the specimen must be physically cut at the first preparation step. An organism as large as 1 mm can be seen at low resolution by conventional ambient temperature SEMs. For higher resolution, the specimen must be available as sets of ''particles,'' whole cells, or sections of cells or tissues. In this case, a cryobased specimen preparation is mostly obligatory.

For TEM, particles smaller than 0.3 to 0.5 μm in height can be directly viewed by cryo-EM or by on-grid negative (positive) staining. The latter should always be

the first approach for any such specimens since it can be done in 5 min with simple technology. Freeze-fracture and shadowing methods can also be applied for isolated particles, especially to see the inner details of membranes in a clearer fashion rather than in the much more limited cross-section profile evident in thin sections. However, the majority of EM studies involve the use of such sections in order to see the detailed ultrastructure within cells. The key question is which approach do I use for (1) structural questions, and (2) immunolabeling questions in the context of ultrastructure.

For purely structural questions for best results, the combination of high-pressure freezing and freeze-substitution is recommended. The hydrated cryosection method may be preferred for some questions when one has access to this technology. If one accepts a potentially lower level of specimen quality one can select one of the two sectioning approaches, plastic embedding or Tokuyasu cryosectioning. Which approach is selected is largely a question of taste; at the top level, the results are often very similar, although the Tokuyasu method has the advantage over conventional embedding in that it avoids solvent dehydration.

For immunolabeling the first question is preembedding versus on-section labeling. Preembedding using immunogold is highly empirical and time-consuming, compared to section labeling. However, when it works, one has the advantage that one has the labeled specimen already embedded in (usually) epoxy resin, which can be cut with standard ultramicrotomes that are widely available. When the labeling is not successful, there is a significantly larger number of variables to adjust than with on-section labeling.

If the antigen is *within* the lumen of a membrane compartment, such as the ER, it makes little sense to try conventional immunogold preembedding labeling because of the difficulties of the antibodies obtaining access to these sites, unless one decides to try to completely open these structures by some means. HRP-based methods can also be used, but one has to accept the fact that this approach is not quantitative and can even be quantitatively misleading.

For the majority of localization questions, on-section labeling is the method of choice. In this approach, each part of every structure has, in theory, an equal choice of being expressed to the antibody on the section surface. In practice, however, the situation is more complex. An important question is whether one should use a plastic-section approach (Lowicryl, LR White etc.) or the Tokuyasu cryosection method. The latter method is faster and recommended for antigens that are less likely to be extracted or artificially mislocalized during the section pickup stage; such artifacts are especially a danger with small, soluble molecules and lipids. It is generally an excellent method for membrane proteins and cytoskeletal proteins; since there is no embedding medium *per se* there is generally more access of antibodies to antigens in the section than is the case for plastic sections, where access is strictly surface-limited. While plastic sections tend to label less than cryosections, they have the advantage that the polymerized resin better ''fixes'' the antigen against redistribution.

In conjunction with freeze-substitution, the low temperature Lowicryl resins offer the ultimate level of specimen preparation that is compatible with immunolabeling.

For small diffusible molecules and lipids, this is absolutely the method of choice. When all methods fail, even with antibodies that give a good signal by light microscopy, the two most likely reasons are, first, lack of accessibility of the antibody to the antigen, even on the surface of the section, and second, the concentration of available antigen on the section surface is simply below detection. A sensible approach is to use similar sections for immunofluorescence analysis that are used for EM; this approach is likely to be more sensitive.

7.8 Final Comment

Given the breadth of techniques available, it is somewhat surprising that the use of more of these EM methods is not sufficiently widespread. Rather than being standard methods in every cell biology institute worldwide, the number of specialist groups has been declining (except for the bare-grid cryo-EM method, which is increasing in use). This problem, and the politics and sociology behind it have recently been discussed in detail. The best possibility to learn these techniques is to visit specialist groups. In addition, practical courses are given in many countries, often sponsored by national EM societies. We teach an annual EMBO-sponsored course in Europe every year. For more details see the websites by Paul Webster and Herb Hagler, which give an excellent overview of many of the techniques mentioned in this chapter. See: (http://www.hei.org/research/scientists/websterbio.htm).and (http://pathcuric1.swmed.edu/Research/haglerEMLab.htm>http://pathcuric1.swmed.edu/Research/haglerEMLab.htm)

Acknowledgments

The need to cover such a broad area of EM obliged me to seek the help of many specialists for this chapter. I would first like to thank my colleagues from the annual EMBO-EM course for their support: Heinz Schwarz, Paul Webster, Herb Hagler, John Lucocq, Marek Cyrklaff, Terry Mayhew, Ivan Raska, Peter Peters, Paul Walther and Kiyoteru Tokuyasu. A number of these friends provided material for figures, acknowledged in the figure legends. Collectively, they also helped me enormously in the writing of the text. I would also like to acknowledge the help of Jacques Dubochet, Bill Earnshaw, Helmut Gnägi, Kenny Goldie, Andy Hoenger, Bruno Humbel, Eduard Kellenberger, Kevin Leonard and Werner Villiger for their input, and, in the case of Bruno Humbel, Jacques Dubochet, Andy Hoenger and Bruno Humbel also for providing beautiful micrographs. Additional excellent images were kindly provided by Kazushi Fujimoto, Shohei Yamashima, Hermann Frank, Christoph Grünfelder, Jean-Luc Murk, Peter Overath, Veronika Neubrand, Anja Habermann and by Robert Ranner of Leica Microsystems, Vienna. Many thanks go also to Herb Hagler, Paul Webster, Heinz Schwarz, Anja Haberman, and Mark Kuehnel for their great support in the preparation of the figures. A special thank to Heinz Schwarz, *to whom this chapter is dedicated*, for giving me the pleasure of seeing his amazing collection of micrographs, the work of over 30 years, that cover almost all the techniques outlined above. Finally, a sad note – In December 2003 Kazushi Fujimoto, a greet pioneer of freeze-fracture immunolabeling passed away at the age of 49. I dedicated this also to his memory.

Keywords

Cryoelectron Microscopy
Imaging of unfixed, unstained biomolecules in a hydrated state after rapid freezing to low temperature (−160 °C).

Heavy-metal Shadowing
Evaporation of a film of heavy metal (e.g. platinum–palladium or tungsten–tantalum) onto a dehydrated preparation. The deposit of metal particles around the biomolecules improves contrast and gives a shadowed, three-dimensional appearance.

High-resolution Autoradiography (EM ARG)
Detection of radiolabeled molecules by coating a stained or shadowed preparation with a film of photographic emulsion. Radioactive emissions hit silver halide crystals in the emulsion, which can be developed into silver grains.

Immunoelectron Microscopy
The application of antibodies to map specific sites on biomolecules. The antibody molecules may be visible after shadowing or negative staining, although detection can be improved by binding of a secondary antibody linked to an electron-dense tag (e.g. ferritin or colloidal gold particles).

Miller Spread
Deposition of dispersed chromatin onto a carbon-coated grid by centrifugation through a denser phase containing sucrose and formaldehyde.

Negative Staining
Instead of staining the biomolecules themselves (positive staining), a solution of heavy-metal salt (e.g. uranyl acetate or sodium phosphotungstic acid) is deposited in the hydrated spaces around and within the molecules.

Replica Casting
Adsorption of biomolecules to a mica surface followed by heavy-metal shadowing and coating of the preparation with a film of carbon. The carbon–metal replica (minus the biomolecules) is then removed from the mica and is mounted on an electron microscope grid for viewing.

Support Film
A thin film of plastic or carbon that is attached to an EM grid and provides a substrate onto which biomolecules can be adsorbed.

Electron microscopy (EM) is a method appropriate for examining details of the sizes and shapes of biological macromolecules and is particularly useful in studying isolated or reconstituted macromolecular assemblies. Small amounts of material (often <1 μg) can be used and prepared in a state suitable for viewing in as short a time as several minutes. The basic procedure involves adsorption of the biomolecules onto a support film, followed by staining or shadowing of the preparation and viewing of the dehydrated molecules *in vacuo* in an electron beam. A resolution of 1 to 2 nm is routine with conventional microscopes. The basic procedure can be adapted to give information about sites of specific epitopes, location of newly synthesized components, internal structures, and atomic composition.

Structures most suitable for EM analysis are nucleoprotein complexes, including ribosomes, spliceosomes, nucleosomes, and virus particles. DNA and RNA molecules are also suitable, and their lengths can be directly related to the number of base pairs or nucleotide residues determined biochemically. In general, it is difficult to visualize small proteins ($<50\,000$ Da), but good detail can be obtained if they are isolated as multimeric complexes or if they can be induced to form filaments or crystalline arrays.

A wide range of applications are available using EM techniques, including virus identification, mapping of hybridized regions in heteroduplexes, detailing of macromolecular interaction, and analysis of the organization of molecular components in replication, transcription, splicing, and translation complexes.

1 Principles

The transmission electron microscope (TEM) consists of a metal column from which air is evacuated and through which a linear beam of electrons is accelerated and focused by electromagnetic lenses. The biomolecules are adsorbed onto a support film, stained and dehydrated (or frozen in an aqueous film on the grid), and introduced into the electron beam through an air lock. Whereas some of the electrons collide with atoms in the specimen, lose energy, and are scattered, the remaining electrons pass through the preparation and are focused to form an image on a phosphorescent screen (for direct viewing) or on a photographic plate (for later examination). Under ideal conditions, a resolution of 0.1 to 0.2 nm can be obtained; however, limitations are imposed by the naturally low masses of atoms (primarily hydrogen, carbon, and oxygen) contained in biomolecules, by distortions and artifacts created during sample preparation, and by radiation damage. Techniques are designed with the following objectives:

1. To minimize distortion by immobilization of the molecules, in their native state, onto an appropriate support.
2. To stabilize molecular complexes by suitable chemical fixation.
3. To improve contrast by staining the preparation with heavy-metal salt or by shadowing with heavy metal.

Irrespective of the method adopted, data derived from the electron microscopic examination of biomolecules should be

entirely consistent with the known biochemical and biophysical properties of the particles. Whenever possible, apparent sizes should be checked by independent measurement of sedimentation rate, electrophoretic mobility, or gel filtration elution. Also, features revealed by EM of isolated molecules should be compared with observations made on them *in situ*, by EM of cell or tissue sections.

2 Techniques

2.1 General

Similar principles of sample preparation (Fig. 1) apply for nucleic acids, proteins, and nucleoprotein complexes, since most of these are less than 20 nm thick and can be adsorbed directly from solution onto the support matrix. The concentration of molecules must be high enough to permit several examples to be viewed together in one field. The efficiency of uptake onto the support is not always predictable, and a range of initial concentrations should be tried. It is important that the biomolecules be held in a solution known to maintain the proper structural features directly prior to applying to the support.

The grid consists of a fine meshwork, usually of copper, which must be coated with a thin support film of plastic (e.g. collodion, parlodion) or carbon. Carbon films are preferable because they are thin (down to 2 nm) and contribute little to the image. However, they are frequently hydrophobic and should be subjected to ionizing gases (by "glow discharging") or should be treated chemically (e.g. with Alcian blue 8GX) to render them hydrophilic before use.

2.2 Nucleic Acids

Nucleic acids are used at a concentration of 1 to 5 μg/μL, and as little as 0.1 μg is required; detailed procedures for working with these molecules may be found in the literature. The molecules can be native DNA or RNA, cloned DNA, single-stranded or double-stranded forms, partially denatured duplexes, or denatured and hybridized structures (Figs. 2–8). A

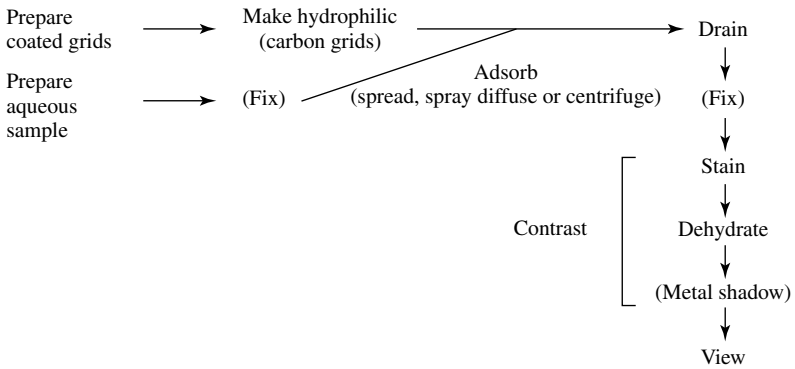

Fig. 1 Flow diagram of the basic procedure. Steps in parentheses are not always used.

key step in their preparation for EM is the spreading out of the molecules so that they can be adsorbed in an extended, nonaggregated form onto the support film. The most successful method of spreading is that devised originally by Kleinschmidt and Zahn (Table 1). The negatively charged nucleic acid is mixed with a basic protein (usually cytochrome c) in a solution appropriate for maintaining the required conformation. This spreading mix, or hyperphase, is spread, via a glass ramp, onto the surface of a second solution, the hypophase, and a molecular monolayer of nucleic acid and protein is formed at the liquid–air interface. Alternatively, the molecular monolayer can be formed by diffusion to the surface of the spreading mix contained in a small vessel or even in a droplet sitting on a hydrophobic surface (Table 2). The nucleic acid–protein complex is adsorbed through brief contact with the support film, stained with ethanolic uranyl acetate, rinsed in ethanol, and air-dried. Protein-free spreading is applied in special circumstances, for instance, to visualize very large DNA molecules that have been stabilized by polyamines (Table 3, Fig. 5). To improve contrast, spread preparations are rotary-shadowing, usually with platinum–palladium, at an angle of 6 to 9° from the plane of the metal vapor. It should be noted that although metal shadowing greatly exaggerates the thickness of the molecules, double-stranded and single-stranded regions can still be differentiated (Figs. 6 and 7).

Cytochrome c should not be used in spreading solutions when experimentally bound proteins are being studied

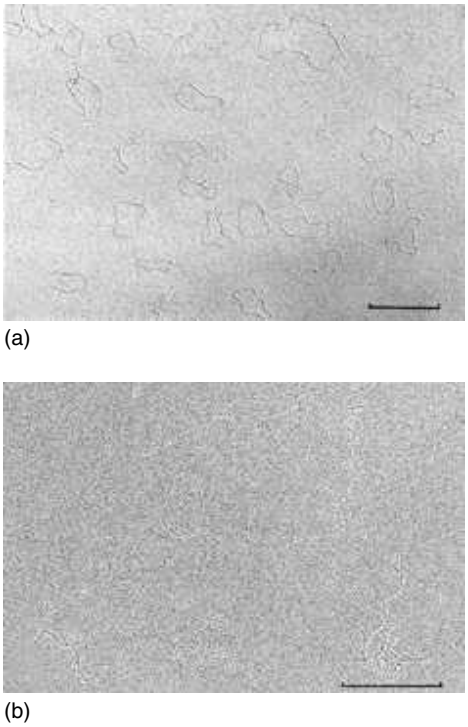

Fig. 2 (a) Simian virus 40 (SV40) DNA spread in the presence of cytochrome c down a glass slide and across a water hypophase. (b) *Xenopus laevis* ribosomal DNA–derived plasmid DNA spread by the cytochrome c microdiffusion droplet technique. The DNA–protein films were picked up on parlodion-coated (a) and carbon-coated (b) copper grids. The use of carbon-coated grids yields a significantly higher proportion of supercoiled molecules and results in a smoother background than is the case for parlodion-coated grids. However, the attachment of molecules to the grid is significantly higher with parlodion. For contrast enhancement, the specimens were rotary-shadowed with platinum/palladium (80 : 20) at an angle of 8°. Note that an additional, very brief, unidirectional shadowing in (a) leads to further contrast enhancement. The bars represent 1 μm.

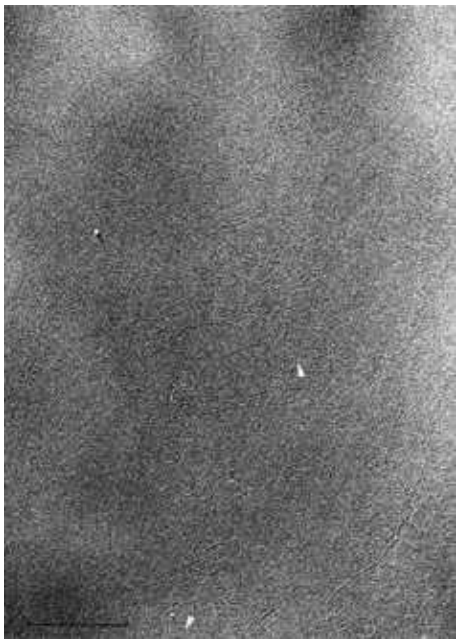

Fig. 3 Herpes simplex virus (HSV) DNA as revealed by the cytochrome c microdiffusion droplet technique, picked up on a carbon-coated grid and shadowed as described in Fig. 2a. Because shearing and stretching forces are minimal when the droplet technique is used, it is possible to spread this extremely large viral genome (150–160 kbp) to its full length. Bacteriophage PM2 circular DNA serves as size markers. The ends of the HSV genome are denoted by arrowheads. Bar represents 1 µm.

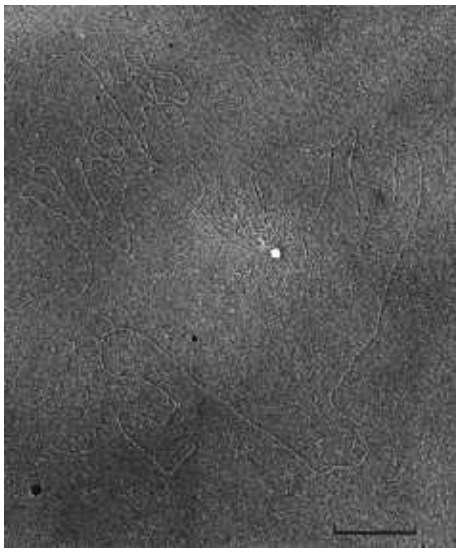

Fig. 4 The ''unraveling'' of the HSV genome out of the viral core as shown by cytochrome c spreading. Complete intact virus particles (see Fig. 17d) were briefly lysed in water and immediately spread onto a water hypophase. The white dotlike structure anchoring the spread DNA represents the unraveled part of the genome, surrounded by fuzzy material, most probably remnants of the viral core. Bar represents 1 µm.

because it obscures fine details of nucleic acid structure. Thus, to permit detection of proteins bound to specific regions of nucleic acid molecules, other protein-free spreading methods have been devised (Fig. 8e). These methods employ low–molecular weight inorganic substances (e.g. benzyldimethylalkylammonium chloride or ethidium bromide) in place of cytochrome c. In working with

Tab. 1 Sequence of steps for spreading nucleic acids.

1. Mix nucleic acid,[a] cytochrome c, and buffer.[b]
2. Pour hypophase solution[c] into a spreading trough.
3. Insert a glass slide in the trough with one end resting on the rim.
4. Apply spreading solution on the glass slide.
5. Wait until solution has run down the ramp and spread out.
6. Touch the film side of a grid[d] to the surface of the hypophase.
7. Stain the grid.[e]
8. Dehydrate the specimen.
9. Rotary shadow for contrast enhancement.[f]

[a]This can be dsDNA (Figs. 2a and 4), ssDNA (Fig. 6a), RNA (Fig. 6c), or heteroduplex molecules (Fig. 7).
[b]Spreading of ssDNA, RNA, or heteroduplex molecules needs denaturing agents, such as formamide and/or urea (Figs. 6 and 7).
[c]Usually, water or ammonium acetate is used; for highly denaturing conditions, formamide can be included.
[d]Normally, carbon- or parlodion-coated grids are used (Fig. 2).
[e]Ethanolic uranyl acetate is widely used.
[f]Usually, platinum/palladium (80 : 20) is used for rotary shadowing at an angle of 6 to 9°; specimens can also be viewed without rotary shadowing (Fig. 8c).
Note: These preparation steps are also used with slight modifications for protein-free spreading procedures (e.g. in the presence of protamines, Fig. 5, or benzyldimethylalkylammonium chloride, Fig. 8e).

Tab. 2 Sequence of steps for spreading nucleic acids: microdiffusion droplet technique.

1. Mix nucleic acid, cytochrome c, and buffer.[a]
2. Put a small drop of the solution on a hydrophobic surface.
3. Leave for 10 to 30 min for diffusion.
4. Pick up nucleic acid–protein film by allowing the grid[b] to touch the surface of the drop.
5. Stain, dehydrate, and shadow.

[a]The procedure yields best results with double-stranded nucleic acids (Figs. 2b, 3, and 8a–d). For spreading single-stranded nucleic acids, denaturing agents, such as formamide and/or urea, have to be added to the solution.
[b]Carbon- or parlodion-coated grids may be used (Fig. 2).

protein molecules bound to nucleic acids, care must be taken to stabilize the complexes before spreading by cross-linking the molecules, in solution, with glutaraldehyde (Fig. 8) or formaldehyde (for chromatin, see Section 2.3). Good detail of the association can be obtained by making a carbon–metal replica of the molecules bound to the surface of freshly cleaved mica. The use of platinum–carbon or tungsten for shadowing reveals finer detail.

2.3 Chromatin

Chromatin spreading techniques are mostly adapted from the procedure devised by Miller and coworkers (Table 4). Large chromatin units are obtained by

Tab. 3 Sequence of steps for protein-free spreading of long DNA molecules.[a]

1. Dilute DNA (0.25–1.6 Mbp) to 4 to 10 ng/µL in microinjection buffer.[b]
2. Apply a 10 µL sample[c] to a freshly glow-discharged carbon-coated grid.
3. Allow DNA to adsorb for 1 min and remove excess liquid by touching the drop with the edge of a filter paper.
4. Immediately add a 20 µL drop of 2% (w/v) aqueous uranyl acetate solution and leave to stain for 20 s.
5. Remove staining solution by touching with the edge of the filter paper and air-dry grid.
6. Rotary shadow[d] and view.

[a]Appropriate for chromosomal lengths of yeast DNA and artificial chromosomes to check molecular integrity prior to microinjection (see Fig. 6).
[b]10 mM Tris-HCl (pH 7.5), 0.1 mM EDTA (pH 8), 100 mM NaCl, 30 mM spermine, 70 mM spermidine.
[c]Transfer of DNA can be achieved without shearing by using a plastic pipette tip with the end cut off.
[d]For instance, platinum : palladium (80 : 20) at an angle of 5°.

Tab. 4 Sequence of steps for spreading large chromatin units: Miller spreading.

1. Incubate cells, isolated nuclei, chromosomes, or chromatin under low ionic strength conditions for chromatin dispersal.
2. Keep on ice for 15 to 30 min.
3. Glow-discharge carbon-coated grids.
4. Fill the well of the centrifugation chamber with a sucrose solution containing formaldehyde.
5. Insert the carbon-coated grid, which is now hydrophilic.
6. Layer a small volume of chromatin solution on top of the sucrose cushion.
7. Centrifuge the chamber (speed and time depend on the equipment used).
8. Remove grid and dry in Photoflo detergent.
9. Stain with phosphotungstic acid and dehydrate.
10. Rotary shadow.

Note: For details see Figs. 9, 10, and 11.

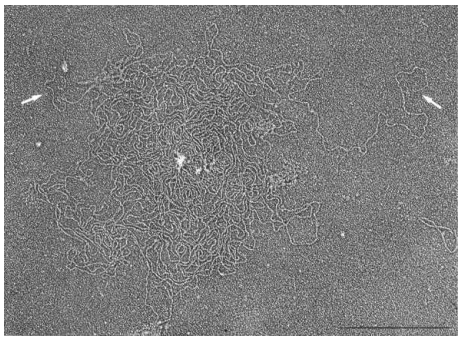

Fig. 5 Full-length chromosomal DNA molecules of approximately 1 Mb isolated by pulse-field gel electrophoresis from *Saccharomyces cerevisiae* strain AB1380 and spread from a buffer containing polyamines and sodium chloride (see Table 3). The long DNA fibres may be stabilized by a coating of polyamines in the presence of sodium chloride and appear to gather into compact bundles. The two ends of a single molecule are indicated by arrows. Bar represents 0.5 µm.

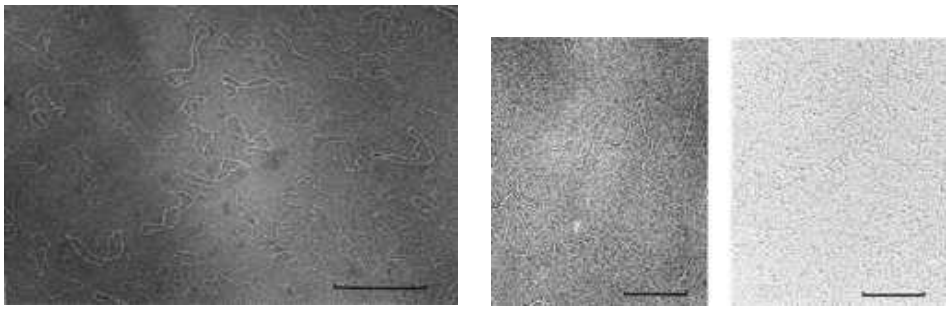


(a) (b) (c)

Fig. 6 (a) Double-stranded and single-stranded DNA of bacteriophage fd spread in 40% formamide, 1 mM EDTA, 10 mM Tris-HCl (pH 8.5) onto a water hypophase. The cytochrome c–DNA film was picked up on a parlodion-coated grid and was shadowed as described in Fig. 2b. The double-stranded DNA molecules are wider with smoother contours than the single-stranded molecules. (b) Replicative intermediate of plasmid pA2Y1, derived from a parvovirus, AAV (adeno-associated virus), spread by the microdiffusion technique in the presence of 10% formamide (parlodion-coated grids, rotary shadowing). The replication eye is denoted by an arrowhead. For contrast enhancement, (a) and (b) are printed in reverse contrast. (c) Tobacco mosaic virus (TMV) RNA was diluted in a spreading solution made from 4 M urea dissolved in ''pure'' formamide, 1 mM EDTA, and 10 mM Tris-HCl, (pH 8.5), heated to 80 °C (5 min), and spread on a 60 °C water hypophase, picked up on parlodion-coated grids, and shadowed. The bars represent 1 μm in (a) and 0.5 μm in (b) and (c).

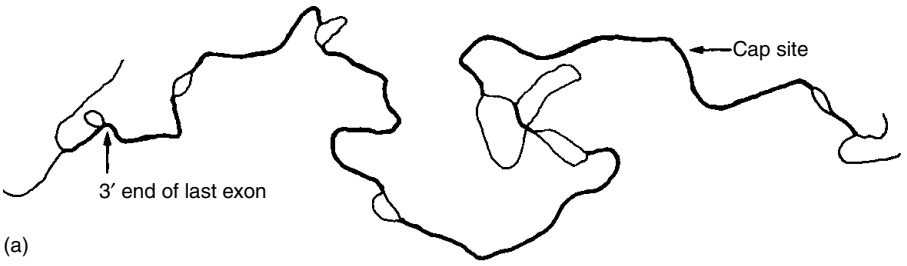
Tab. 5 Sequence of steps for spreading small chromatin units.

Part A
1. Dilute chromatin for dispersal under conditions of low ionic strength.
2. Place a drop of chromatin solution on a hydrophobic surface.
3. Place a glow-discharged carbon grid on top of the drop.
4. After 15 min, remove the grid and place it on top of a drop of double-distilled water.
5. After 10 min, transfer it to a second drop of water.
6. After 10 min, remove the grid; negative-stain and air-dry the preparation.
7. Rotary shadow for contrast enhancement (see Figs. 12a, b, and d)
Part B
1. Hold a glow-discharged, carbon-coated grid with forceps.
2. Apply a drop of chromatin solution.
3. Allow the chromatin to adsorb onto the film for 1 to 2 min.
4. Stain and air-dry (alternatively shadow) (see Fig. 12c).

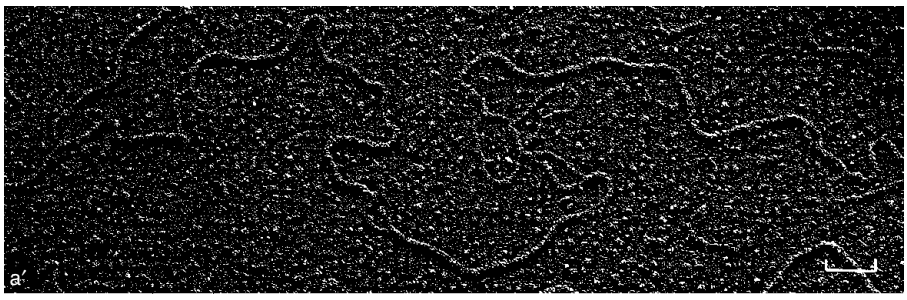
lysing cells or nuclei in a low salt concentration, high pH buffer (often referred to as ''pH 9 water''). The chromatin is left to disperse and is then centrifuged at low speed, through a denser solution containing fixative (formaldehyde), onto the surface of a carbon-coated grid. The grid is dipped into a solution of wetting agent (Kodak Photoflo 200) and air-dried. The preparations can be positively stained (with ethanolic phosphotungstic acid), negatively stained (with aqueous uranyl acetate), or metal-shadowed. Chromatin spread from avian erythrocytes

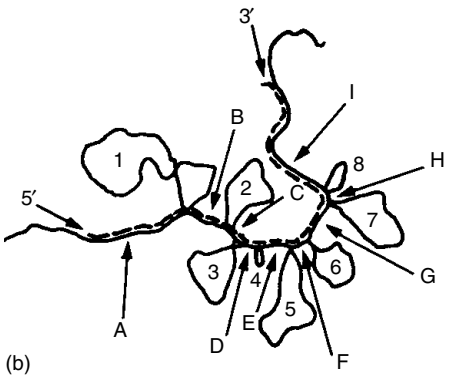
shows the typical nucleosomal configuration of dispersed chromatin (Fig. 9). The features of actively transcribing chromatin can be seen in nucleolar (pre-rRNA) units (Fig. 10). In contrast, nonnucleolar transcription units normally contain more widely spaced nascent transcripts (Fig. 11b).

For small chromatin units, such as chromatin fragments and viral chromatin (minichromosomes), high-speed centrifugation is required to deposit the chromatin onto the coated grid. Alternatively, small chromatin units can be adsorbed directly by floating the grid, carbon film down, on the surface of a droplet containing the sample (Table 5). The nucleosomal configuration of simian virus 40 chromatin (the SV40 minichromosome) is shown in Figs. 12a to c. Supranucleosomal

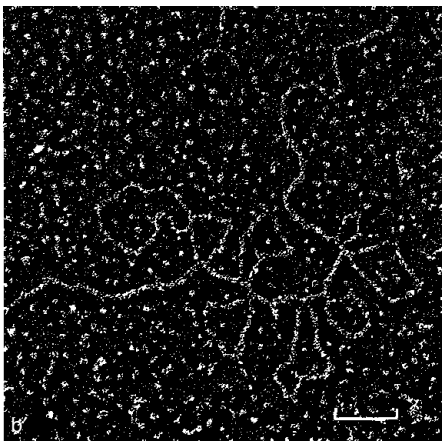


(a)





(b)



particles – for instance, those obtained by brief nuclease digestion of avian erythrocyte chromatin (Fig. 12d) – are also prepared by direct adsorption.

2.4 Proteins

The most commonly used method for contrast enhancement of proteins is negative staining (Table 6). This method is extremely rapid and involves drying of an aqueous solution of heavy-metal salt (e.g. uranyl acetate) with the protein molecules on the coated grid. The metal salt occupies hydrated regions in and around the biomolecules and, upon drying, forms a dense cast. Since the biomolecules themselves are not stained, but the background is stained, a negative image is created. This technique has been used extensively for examining protein filaments. Negatively stained intermediate filaments, in this example, glial fibrillary acidic protein (GFAP), are shown in Fig. 13a. Details of the arrangement of individual collagen molecules within the collagen fibril can be obtained from preparations like that seen in Fig. 14.

An alternative to the adsorption of proteins from droplets is to spray them, in aerosols, onto the surface of carbon-coated grids. The spraying is most easily achieved

Tab. 6 Sequence of steps for negative staining.

1. Hold a coated grid[a] with forceps.
2. Apply a drop containing biological material to the grid.
3. After 10 to 60 s, drain off excess liquid.
4. Apply a drop of negative stain[b] for 10 to 60 s.[c]
5. Remove liquid and air-dry the preparation.

[a]Carbon, parlodion, or sandwich coats (made from Formvar and carbon) may be used. Glow discharge increases the amount of biological material adsorbed onto the film; plastic films, however, are destroyed by glow discharge.
[b]Uranyl acetate and phosphotungstic acid are widely used for negative staining.
[c]Alternatively, the grid can be transferred through several drops of stain.
Note: For details on the various procedures, see Figs. 13–18.

Fig. 7 (a) A DNA : DNA heteroduplex formed between cloned mouse tyrosine aminotransferase (TAT) and rat TAT. Heteroduplexes were formed after denaturation in 0.1 M NaOH, 20 mM EDTA at 20 °C for 10 min and renaturation in the presence of 50% formamide, 20 mM Tris-HCl (pH 7.2) at 20 °C for 90 min. Heteroduplexes were then prepared from a spreading solution containing 4 M urea dissolved in ''pure'' formamide, 1 mM EDTA, 10 mM Tris-HCl, (pH 8.5) on water hypophase, followed by rotary shadowing. (a′) The interpretive drawing of (a): the positions of the cap and of the 3′ end of the last exon are indicated. (b) A heteroduplex formed between poly(A+) RNA from bovine muscle epidermis and a genomic clone that contains the gene coding for epidermal bovine keratin (KBla). Heteroduplexes were formed in 70% formamide, 0.3 M NaCl, 1 mM EDTA, 20 mM Tris-HCl (pH 8.0). The sample was kept for 17 h at 62 °C, followed by incubation at 64 °C for 2 to 4 h. The hybrids were prepared for electron microscopy as described in (a). (b′) The interpretative drawing of (b): DNA is represented by a continuous line, RNA by an interrupted line; the 5′ end of mRNA is identified by a change in molecular diameter and the 3′ end by a projecting [i.e. nonhybridized, poly(A) tail]. Exons are denoted by capital letters, introns by arabic numerals. For contrast enhancement, (a) and (b) have been printed as negatives. Bars represent 100 nm.

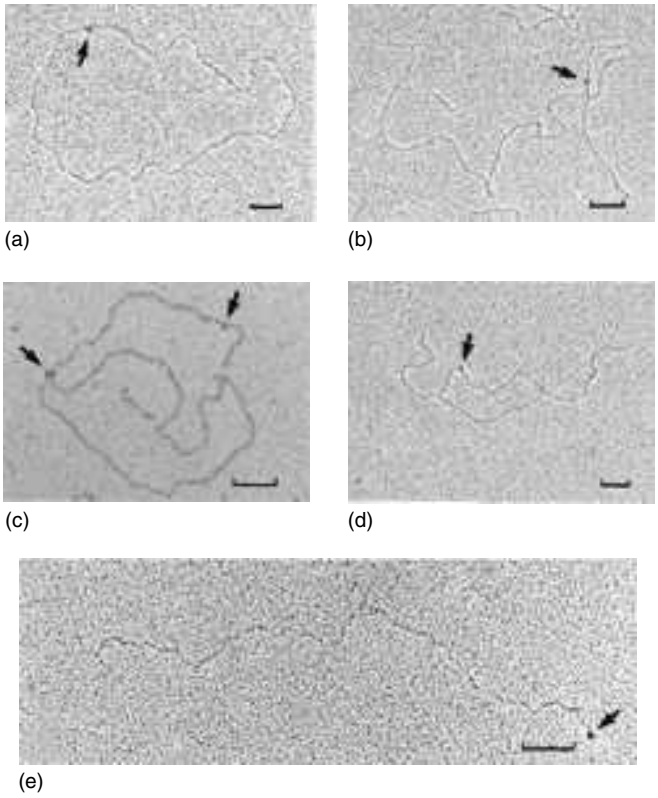


Fig. 8 (a, b) Binding of monoclonal Z-DNA antibodies to DNA from bovine papillomavirus (BPV-1). Antibodies against left-handed Z-DNA were incubated and cross-linked with 0.1% glutaraldehyde (2 h) to the pML2d-BPV-1 plasmid DNA (a). To determine the position of the binding site, the DNA was digested with the single-cutting restriction enzyme Xba I (b). Arrows indicate the position of Z-DNA antibodies on the plasmids. (c, d) Localization of large-tumor antigen (T antigen) on replicative intermediates of SV40 DNA. The molecules were immunostained with either ferritin-labeled protein A (c) or ferritin-labeled goat antimouse antibodies (d) after cross-linking with 0.1% glutaraldehyde (20 min, 37 °C). To localize T antigen on the replicated section, the complex was cleaved with the single-cutting enzyme Bgl I. Arrows indicate the ferritin-labeled T antigen on DNA. These complexes (a–d) were prepared for electron microscopy according to the cytochrome c droplet diffusion technique. The specimens were rotary-shadowed, except the one shown in (c), which is only stained by ethanolic uranyl acetate. (e) DNA-relaxing enzyme molecules linked to single-stranded SV40 DNA (arrow). After enzyme reaction, the complexes were spread from a solution containing 0.25 M NaOH, indicating that the protein dot is stable in alkali and is therefore linked via a covalent bond to the end of the single-stranded DNA. Enzyme–DNA complexes were prepared with a protein-free spreading procedure using benzyldimethylalkylammonium chloride (BAC) and were shadowed. Bars represent 100 nm.

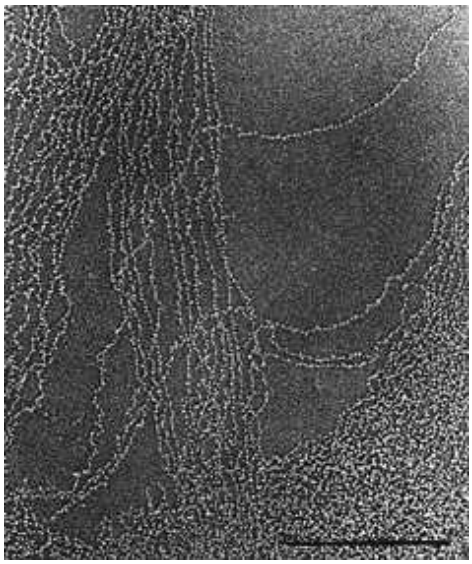

Fig. 9 Appearance of the nucleosomal chromatin configuration of chicken erythrocytes lysed and swollen in 0.5 mM sodium borate buffer (pH 8.8) for 5 min, spread by the Miller technique, positively stained, and metal-shadowed. The dispersed chromatin shows the characteristic nucleosomal ''beads-on-a-string'' organization. Bar represents 1 μm.

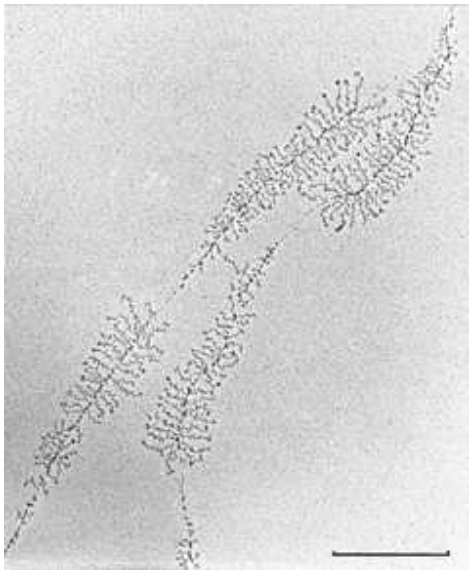

Fig. 10 Organization of nucleolar chromatin from oocytes of the newt *Pleurodeles waltlii*, after spreading using the Miller technique, positive staining, and rotary shadowing. The transcribed chromatin segments are densely packed with RNA polymerases and nascent ribonucleoprotein (RNP) fibrils. The tandemly arranged active pre-rRNA genes are interspersed by the spacer regions. The axis of the spacer is relatively thin and does not show nucleosome-sized particles. Bar represents 1 μm.

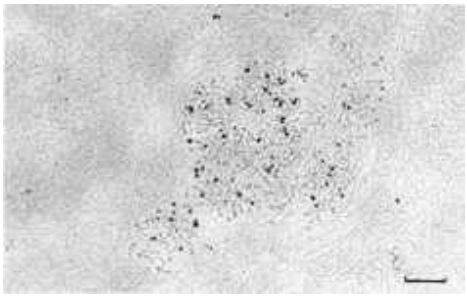
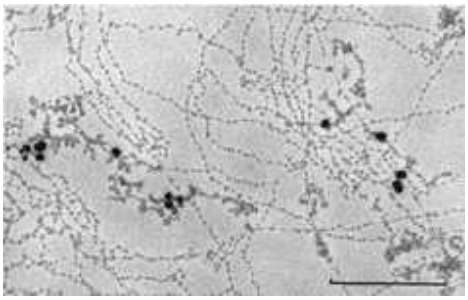
by touching the tip of a glass capillary tube, containing both sample and stain, into a stream of nitrogen. Elongate, or rod-shaped, proteins can be mixed with glycerol (and no stain) and sprayed onto the surface of a piece of freshly cleaved mica. The deposit is then shadowed finely and carbon-coated to produce a replica cast of the protein molecules. (Details are provided in the literature.) Unidirectionally



(a)



(b)

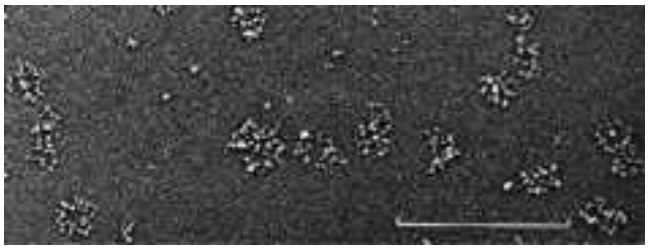
Fig. 11 High-resolution autoradiography of chromatin spread from mouse P815 cells after labeling for 5 min with [^{3}H]uridine. (a) Radioactivity (recorded as dense silver grains) associated with densely transcribing regions showing the gradient-like features of pre-rRNA transcription units (cf. Fig. 10). The background consists of many strands of nucleosomal chromatin. (b) Radioactivity associated with individual RNP fibrils characteristic of those found in nonnucleolar transcription units. In sparsely transcribing units, nucleosomes can be seen on the chromatin strand between the nascent transcripts. Both preparations were stained with phosphotungstic acid, rotary-shadowed with platinum, and exposed with Ilford L4 emulsion. Bars represent 0.5 μm. (Courtesy of S. Fakan, with permission from Springer-Verlag.)

Fig. 12 Small chromatin units such as SV40 chromatin complexes (a–c) or supranucleosomal particles from chicken erythrocyte chromatin (d) are prepared by direct adsorption to freshly glow-discharged, carbon-coated grids. The chromatin is allowed to adsorb onto the film for 1 to 2 min, stained with 2% uranyl acetate (c), and rotary-shadowed (a, b, d). Under spreading conditions involving buffers of low ionic strength (2 mM EDTA, 1 mM Tris-HCl, pH 8.4), the SV40 nucleoprotein complexes (''minichromosomes'') show the typical ''beads-on-a-string'' morphology of the circular nucleosomal chain (a, b). The foreshortening of DNA in the SV40 ''minichromosomes'' due to nucleosomal organization is demonstrated by comparison with the viral DNA, which is included in the preparation (b). This packaging of the SV40 genome, at first-order level into nucleosomes, results in a foreshortening ratio of about 5.5 : 1. (d) At the second level of packaging, chromatin is organized into supranucleosomal structures. Fractions of supranucleosomal granular subunits, obtained by brief digestion of chromatin with micrococcal nuclease at physiological salt concentration, can be spread after fixation for 15 min at 4 °C with glutaraldehyde (final concentration 0.2%). (e) Nonnucleosomal forms of chromatin beside nucleosomal chains are observed in Miller spread preparations of African green monkey kidney cells (RC37) after infection with herpes simplex virus (HSV). The ''bubblelike'' configurations, thickly coated with a single-strand DNA-binding protein, alternate with unbranched thin intercepts (staining and shadowing as in Figs. 9 and 10). Bars represent 500 nm in (a), (d), and (e), 200 nm in (b), and 50 nm in (c).

shadowed molecules, prepared by the spray/replica technique and representing early stages in the assembly of GFAP filaments, are shown in Fig. 13b.

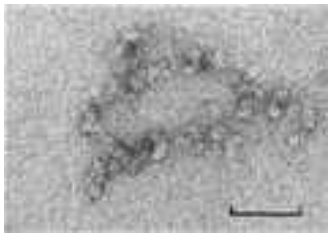
2.5 Macromolecular Assemblies

Multimeric enzyme complexes, ribosomes, viruses, and other particles can be treated in ways similar to those described for protein filaments or for small chromatin units. Particles in the size range of 10 to 200 nm diameter are excellent targets for negative staining (Figs. 15–18), which often reveals considerable detail of surface structure (Fig. 17). Nevertheless, the size of the particles of dried stain (or of the metal particles after shadowing) limits the resolution of structural

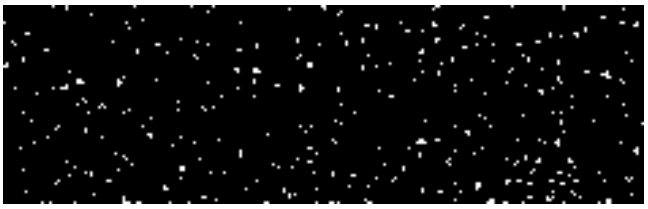


(a)

(b)

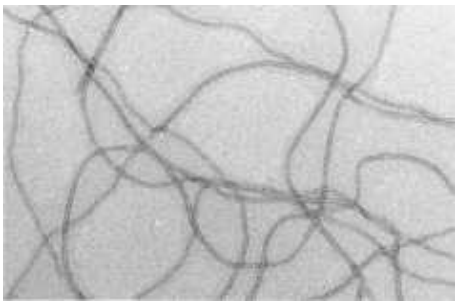


(c)

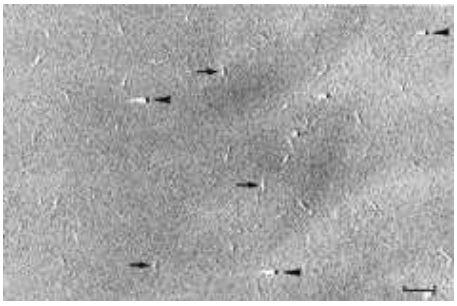


(d)

(e)

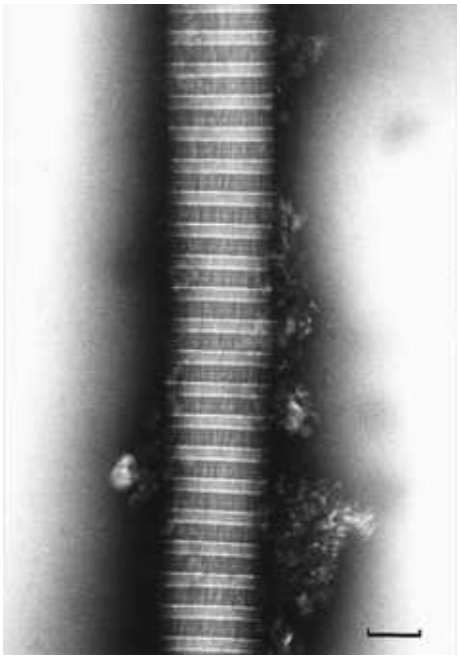


(a)



(b)

Fig. 13 Intermediate filaments as visualized by negative staining and partly assembled monomers as visualized by metal shadowing. (a) GFAP intermediate-sized filaments spread onto carbon film and negatively stained with 1% w/v uranyl acetate. GFAP was prepared from spinal cord and assembled *in vitro* by dialysis against the following buffer: 10 mM Tris-HCl (pH 7.0), 1 mM $MgCl_2$, 50 mM NaCl, and 25 mM 2-mercaptoethanol. Note that the intermediate filaments are 10 nm in width and are long with smooth edges. (b) The assembly of intermediate filaments can be arrested at various points along the assembly pathway by choosing the appropriate buffer conditions. In this preparation, GFAP molecules containing chains of four proteins were formed in 10 mM Tris-HCl (pH 8.5). A sample of this was made 50% v/v in glycerol, sprayed onto freshly cleaved mica, and unidirectionally shadowed at 10° with platinum. The replica was then floated on water and picked up onto grids. The molecules of GFAP appear as short rodlets, between 45 and 65 nm long and 2 to 3 nm wide (arrows). Latex beads demonstrate the direction of shadow and locate the position of the droplets on the replica (arrowheads). Both micrographs are shown at the same magnification; bar represents 100 nm. (Courtesy of R. Quinlan and A. M. Hutcheson.)



detail. A superior technique cryoelectron microscopy involves the rapid freezing of a thin (100 nm) aqueous film containing the specimen particles. Below −143 °C, water can be held in a vitrified state, which resembles the liquid state and avoids formation of ice crystals. In this condition, macromolecules and macromolecular assemblies can be viewed free of artifacts from fixation, dehydration, and staining. Under-focus phase contrast is used to produce a high-resolution image.

Fig. 14 A collagen fibril, negatively stained with 4% phosphotungstic acid, on a glow-discharged, carbon-coated grid. The staggered arrangement of the collagen molecules in the fibril results in the striated appearance after negative staining. The bars represent 100 nm.

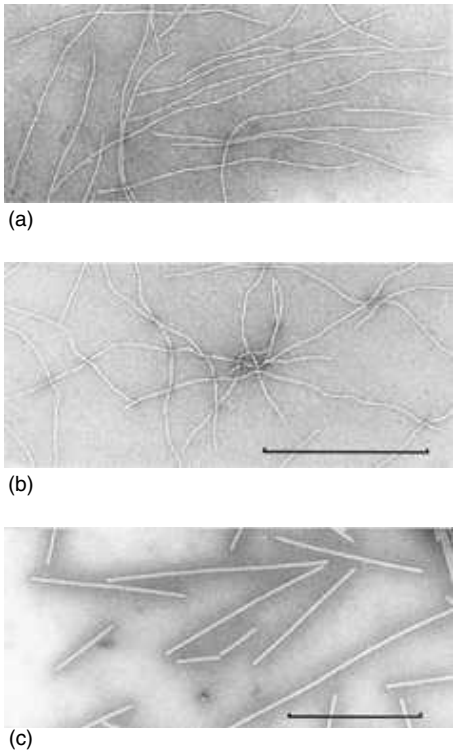


Fig. 15 Examples of filamentous bacteriophages and rodlike viruses. The bacteriophage fd was negatively stained with either 4% phosphotungstic acid (a) or 2% uranyl acetate (b). The tobacco mosaic viruses in (c) are stained with 4% phosphotungstic acid. All preparations were made on carbon-coated, glow-discharged grids. The bars represent 0.5 µm.

3 Applications

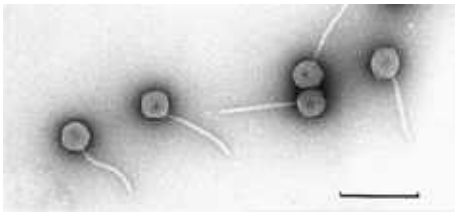
3.1 Use of Antibodies

Antibody molecules (IgG and IgM) are large enough to be resolved in metal-shadowed or negatively stained preparations. Monoclonal antibodies can be used to map sites on nucleic acid or protein molecules and to identify individual components within macromolecular assemblies. Antibodies can also be used to build up denser structures around small

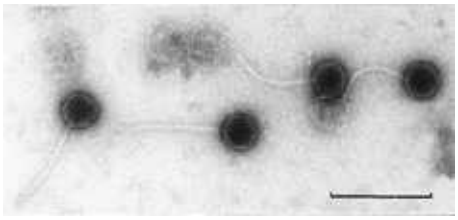
Tab. 7 Sequence of steps for immunogold labeling: identification of individual components in macromolecular assemblies.

1. Hold a coated grid[a] with forceps.
2. Apply a drop containing biological material to the grid.
3. After 1 min, wash the grid with 20 drops of double-distilled water from a Pasteur pipette and drain off excess liquid.[b]
4. Place the grid (film side down) on a drop[c] of the primary antibody diluted in phosphate-buffered saline (PBS), 1% bovine serum albumin (BSA).[d]
5. After 30 min, remove the grid and place it on top of a drop of PBS, 1% BSA.
6. After 5 min, transfer the grid to a fresh drop of PBS, 1% BSA; repeat this washing step a third time.
7. After 5 min, transfer the grid to a drop of the gold-labeled secondary antibody[e] diluted in PBS, 1% BSA.
8. After 30 min, place the grid on top of a drop of PBS, 1% BSA and continue as described in step 6.
9. Wash the grid as described in step 3.
10. Stain the specimen with 2% aqueous uranyl acetate for 1 min and air-dry.

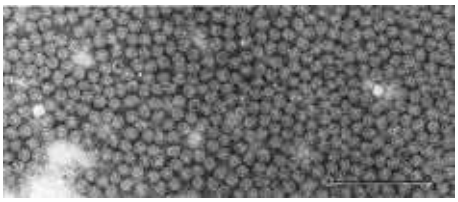
[a] The procedure yields best results with glow-discharged carbon-coated grids.
[b] Never drain the grids completely.
[c] Droplets are placed on a piece of Parafilm.
[d] PBS, 1% BSA; filtered through a 0.22 µm Millipore filter.
[e] Alternatively, a protein A–coated colloidal gold probe may be used.



(a)



(b)



(c)

Fig. 16 Examples of tailed (a, b) and globular (c) bacteriophages. Bacteriophage λ (a) and the globular bacteriophage fr (c) were stained with 4% uranyl acetate. The bacteriophage T5 (b) was stained with 2% uranyl acetate. Note the empty phage heads in (b). All preparations were made on freshly glow-discharged, carbon-coated grids. The bars represent 200 nm.

proteins, which are themselves difficult to resolve. Secondary antibodies tagged with electron-dense markers such as ferritin (Figs. 8c and d) or colloidal gold particles are routinely used to improve detection (Table 7). For instance, gold-conjugated secondary antibodies can be used to detect a range of epitopes in recombinant viral coat particles (Fig. 18). A quite different application is the use of anti-biotin to detect biotinylated nucleic acid probes that have been hybridized to complementary sequences in chromatin preparations or *in situ* in isolated chromosomes. In the example shown in Fig. 19, two different antibody-binding sites are enhanced for EM detection by addition of a common secondary antibody tagged with colloidal gold particles. In this way, specific genes can be detected within complex chromatin masses.

Tab. 8 Sequence of steps for high-resolution autoradiography of biomolecules.

1. Radioactively label[a] living cells or subcellular fractions *in vitro*.
2. Isolate molecules or molecular complexes and prepare by direct adsorption on the grid or by spreading techniques.
3. Stain,[b] dehydrate, and rotary shadow.
4. Evaporate a thin layer of carbon (4–8 nm) on the specimen.[c]
5. Coat the specimen with a layer of photographic emulsion.
6. Follow the gold latensification–Elon–ascorbic acid (GEA) procedure.[d]
7. Transfer to Elon–ascorbic acid developer.
8. Transfer into the fixing bath.
9. Wash and air-dry.

[a]Generally, radioactive tritium is used.
[b]Negative or positive staining; shadowing with platinum/palladium.
[c]The fine coat prevents chemical interactions between specimen and emulsion.
[d]The GEA development procedure increases the sensitivity and gives rise to silver grains of rather small size.

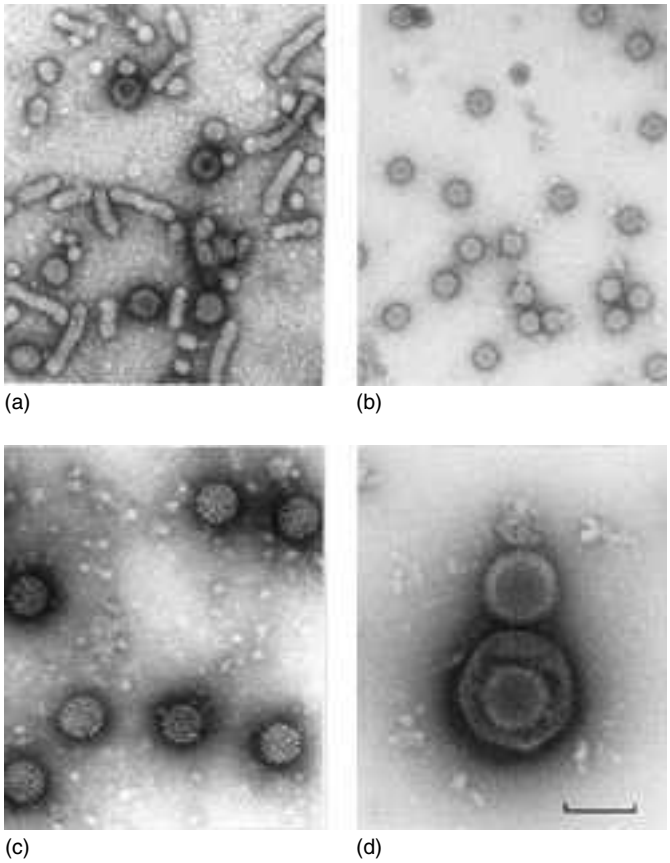


Fig. 17 Details of virus structure revealed in negatively stained preparations on carbon-coated, glow-discharged grids. (a) Hepatitis B viruses (HBV) were stained with 2% uranyl acetate. (b) Polioviruses and (c) bovine papilloma viruses (BPV) were stained with 4% phosphotungstic acid. (d) Herpes simplex virus (HSV) was stained with 2% uranyl formate. HBV was obtained from a patient's serum and reveals, in addition to the mature ''Dane'' particles, globular and filamentous forms of the viral S protein (a). Polioviruses show a fine-textured surface (b), while BPVs reveal a moruloid structure, which is due to the capsomere architecture (c). This organization is also visible in the HSV capsid, even when surrounded by the envelope (d). The micrographs are magnified to the same scale to give an impression of the size difference between the virus families. Bar represents 100 nm.

3.2 Detection of Radiolabeled Molecules

Although high-resolution autoradiography (EM ARG) is applied mostly to the detection of newly synthesized (radiolabeled) components *in situ* at the cellular level, application is possible with spread molecules and molecular complexes. However, EM ARG is limited to the use

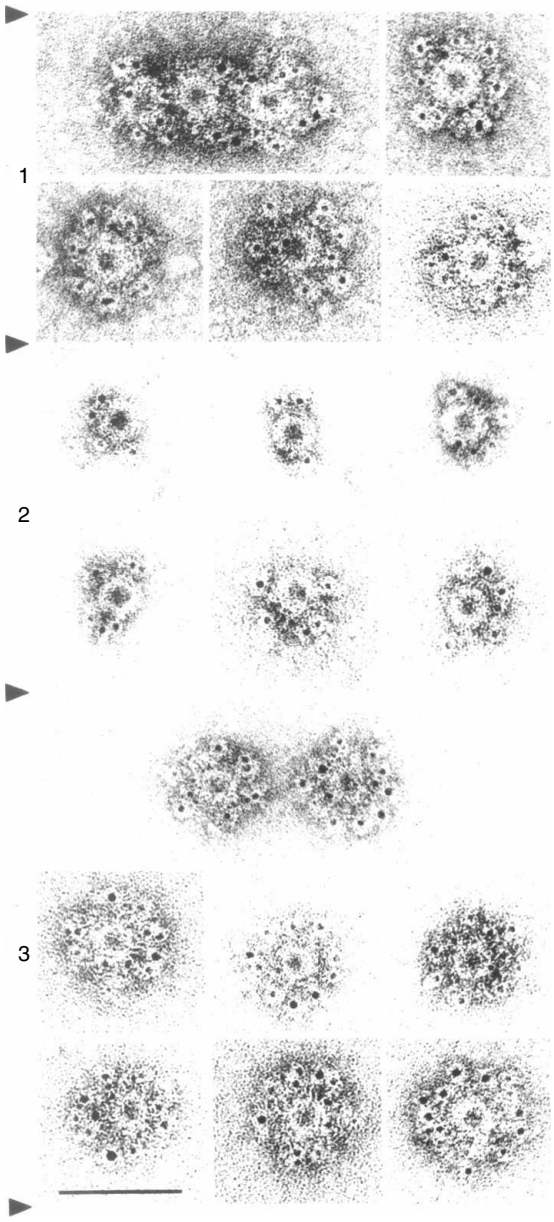

Fig. 18 Detection of different epitopes in recombinant viral core particles. The vector cassette pB–CHG–HBc (C, cytomegalovirus (CMV) promoter; H, histidine tag; G, green fluorescent protein; HBc, core protein of hepatitis B virus) was transfected into HeLa cells. The recombinant core particles were isolated by sucrose gradient centrifugation. Epitopes in the fusion protein were detected by immunoelectron microscopy after adsorption of the particles onto carbon-coated grids. All incubation and washing steps were carried out on the grids. The antibodies used were (1) rabbit anti-HBc/goat antirabbit –5 nm gold; (2) mouse anti-histidine/goat antimouse –5 nm gold; and (3) rabbit anti-GFP/goat antirabbit –5 nm gold. After immunoreactions, the grids were negatively stained with uranyl acetate. Bar represents 100 nm.

of radioisotopes emitting soft β-particles, usually ^{3}H. Molecules that have been radiolabeled either *in vivo* or *in vitro* are prepared for EM by the method most appropriate for that type of sample (Table 8). After staining, the preparation is covered, first with a thin protective coat of carbon and then with a layer of photographic emulsion. Ideally, the emulsion should consist of a homogeneous monolayer of

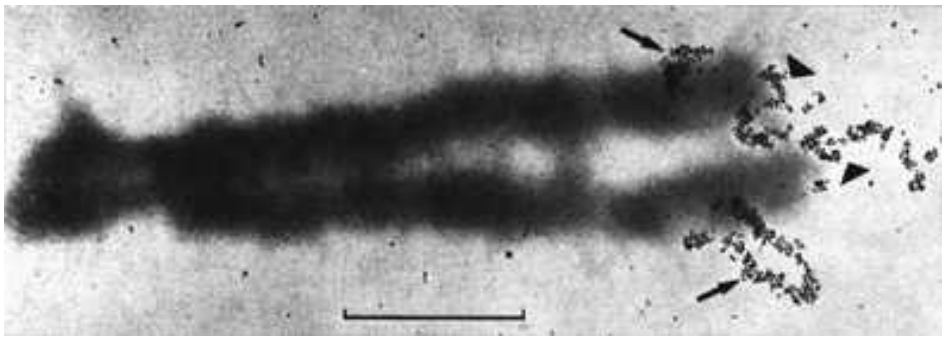

Fig. 19 Whole-chromosome mount from *Xenopus* culture cells after *in situ* hybridization with a mixture of biotinylated DNA encoding tRNA and oocyte-specific 5S RNA. The chromosomes are partially unfolded, and the sites of hybridization are detected using anti-biotin and secondary antibodies tagged with colloidal gold. The gold particles are seen to decorate DNA loops containing tRNA genes (arrows) and 5S RNA genes (arrowheads). The bar represents 2 µm. (Courtesy of S. Narayanswami and B. A. Hamkalo, with permission from Oxford University Press.)

the silver halide crystals. After being kept in the dark, to allow a sufficient amount of radioactive decay, the emulsion is developed, leaving silver grains above the sites of radiolabeling in the molecules. EM ARG is subject to two severe limitations:

1. The accuracy with which the developed silver grain can be located to the source of radiation in the specimen molecule. This depends on the thickness of the preparation and the diameter of the silver halide crystal in the emulsion and results in scattering of grains with a half distance of about 100 nm.
2. The efficiency in detecting radioactive disintegrations. Even molecules labeled to high specific activities require exposure times of generally more than a few weeks.

In spite of these limitations, EM ARG has been used successfully in studying sites of replication in isolated DNA molecules and the location of active transcription complexes in spread chromatin (Fig. 11).

3.3 Electron Spectroscopic Imaging (ESI)

By adapting the electron microscope to include an imaging electron energy filter, positional information can be recovered from electrons that have lost a specific and characteristic amount of energy in colliding with atoms in the specimen molecules. This approach has been used successfully in the location of phosphorus atoms, particularly those in the phosphodiester bonds of nucleic acids. The resulting electron spectroscopic imaging (ESI) has been used to delineate the path of the sugar–phosphate backbone in nucleosomes and the configuration of SRP–RNA (7SL RNA) within the signal recognition (ribonucleoprotein) particle. Along with related techniques in element mapping within biomolecules and their complexes, ESI is becoming increasingly sophisticated and promises many diverse applications.

3.4
Image Reconstruction

Individual molecules, under optimum conditions of spreading and staining, give weak and ill-defined images. To improve on the amount of structural detail, information from many molecules can be combined to smooth out random variations between images. To do this, it is necessary to use molecules (e.g. protein filaments), which contain regular, repeating arrays of subunits. Alternatively, the biomolecules can be induced to form crystalline arrays of regular, tightly packed, oriented units. Electron micrographs of arrays of these types can then be used for image processing to produce enhanced structural detail.
